Autism and the Caribbean

Shirley Alleyne

School of Clinical Medicine and Research, The University of the West Indies, Cave Hill, St. Michael, Barbados

Historical Background

The Caribbean comprises over 700 islands, islets, reefs, and cays between North and South America. It is inhabited by approximately 42 million persons. Although many similarities exist between the islands and territories, there are huge variations in the following areas: population, gross domestic product, languages, educational status of the populous, and the healthcare systems. This report captures the status of autism in 12 of the English-speaking countries and territories of the Caribbean (Anguilla, Antigua and Barbuda, the Bahamas, Barbados, Dominica, Grenada, Jamaica, Saint Kitts and Nevis, Saint Lucia, St. Vincent and the Grenadines, Tortola, and Trinidad and Tobago) with information on published research from the English- and Dutch-speaking Caribbean.

There is a dearth of published data on the history of autism in the Anglophone Caribbean. Up until the late twentieth century, a minimum level of basic knowledge, lack of appropriate resources (health, educational, and social), stigma, and discrimination resulted in many individuals with developmental disabilities being hidden away at home or housed in mental institutions. Over the last two decades, there have been a number of drivers for addressing the needs of the disabled community, starting with the adoption of the Panama Commitment to Persons with Disabilities in the American Hemisphere by the Organization of American States (OAS) in 1996 and more recently the signature of the Convention of the Rights of Persons with Disabilities by all of the island states within the last decade (Collamarco et Delamonico 2013). On a regional level, the importance of addressing autism was first

discussed by Heads of Government in the context of a larger discussion on special needs and disability during the 34th regular meeting of the Caribbean Community (CARICOM) Heads of Government in the Port of Spain in July 6, 2013. The call to address special needs and disabilities with a higher-level meeting was raised by Haiti and led by the Prime Minister of the Bahamas the Honorable Perry Christie and Prime Minister of Trinidad and Tobago the Honorable Kamla Persad-Bissessar who reported that their child and grandchild, respectively, are autistic.

Services

No center in the English-speaking Caribbean offers services exclusively for autism. Over the last 40 years with increasing awareness of the need to identify and address early developmental

challenges in children, the power of early intervention, and the rights of all children, the number of child development centers throughout the region has grown (see Table 1). These centers cater to children with all forms of disability, including autism. The most recent additions have been the Marjorie Davis Institute which opened in the Bahamas on April 21, 2015, and the Autism Centre in the British Virgin Islands on October 29, 2012. The Autism Centre in Tortola initially exclusively provided services for children and adults on the autism spectrum; however, its function has evolved to include the provision of services for other disabilities. This evolution captures a trend that resonates throughout the region. Some of the child development centers are publicly funded; however, the majority are formed by non-governmental organization and receive significant subventions from the government and

Autism and the Caribbean, Table 1 Centers providing evaluation or treatment for autism

Country/territory	Centers providing autism services	Services provided	Free services
Bahamas	The Marjorie Davis Institute	Evaluation and treatment	Yes
	Caribbean Center for Child Development	Evaluation and treatment	No
Barbados	Albert Cecil Graham Development Centre	Evaluation and treatment	Yes
	Sunshine Early Stimulation Centre	Treatment	No
	The School for Special Needs	Treatment	No
	The Irvine Wilson School	Treatment	Yes
British Virgin Islands	The Autism Centre	Evaluation and treatment	Yes
Dominica	The Alpha Center	Treatment	No
	The Achievement Centre	Treatment	No
Jamaica	The Pediatric-Adolescent Clinic University Hospital, Kingston	Evaluation	No
	The Early Stimulation Centre and the Early Stimulation School	Evaluation and treatment	Yes
	The Montego Bay Autism Center	Treatment	No
	The McCann Child Development Centre	Treatment	No
	The Promise Learning & Training Centre	Treatment	No
St. Lucia	Child Development Guidance Clinic	Evaluation and treatment	Yes
Trinidad and Tobago	Child Development Clinic, Eric William Complex, Mount Hope	Evaluation	Yes
	The Child Guidance Clinic	Evaluation	Yes
	The Mental Health Clinic, San Fernando	Evaluation	Yes
	The Mental Health Clinic, Tobago	Evaluation	Yes
	The Autism Society of Trinidad and Tobago	Treatment	Yes

donations from philanthropic associations. Their budgets are extremely vulnerable to the fiscal adjustments that frequently occur in small developing economies. This situation also pertains to most of the private special education schools; some of which have closed as a result of inadequate funding.

There are extensive wait periods to access services in the public centers and clinics (up to 3 years in some countries). The extensive wait adds to the delay in diagnosis and commencement of interventions and adversely impacts outcomes. A significant minority of children access services in the private sector where the availability of trained professionals is often greater than the public sector. An effort to expand and decentralize services has been made in Barbados with the addition of speech and language therapy in some of the public clinics. Additionally the evaluation and treatment services are slowly increasing with greater awareness of autism and the benefits of early intervention.

The identification of autism sometimes occurs as a result of concerns raised during routine developmental assessments by pediatricians. However for many of the children who receive services in the public sector, concern about the child's socio-communicative development first occurs in the preschool and elementary school environments. It is also in the school environment that most children receive intervention.

For a vast number of children and adolescents who are identified, the main intervention is placement in a special education class with children who have other developmental disabilities. One-on-one instruction, routine application of applied behavioral analysis, Treatment and Education of Autistic and Related Communication Handicapped Children (TEACCH), and other evidence-based interventions are more common in private schools but seldom present for the majority of children who receive services in the public sector. Where evidence-based interventions for teaching children with autism are available, very few children receive the recommended 20–40 h per week. Speech and language therapy and occupational therapy are seldom integrated into the education system; these therapies are more likely to be integrated in the education plan

of children with autism who attend private schools. The availability of specialists and frequency of receipt of these services vary across the countries and territories with St. Vincent and the Grenadines (population, 109, 000) reporting no speech and language therapist on the island. Parents will often access psychoeducational testing, speech and language, occupational therapy, and behavior therapy privately; the cost of these services presents an additional financial burden in already difficult circumstances.

Some countries maintain a database of persons with disabilities, and in Jamaica the University of the West Indies maintains an autism database; however no other national registry of persons with autism was identified during the preparation of this chapter. Additionally outside of Jamaica and Aruba, no documented monitoring of the situation of persons with autism or studies in the area of autism were identified.

The University of the West Indies, Department of Child and Adolescent Health, Mona campus (Jamaica) has been the major center for research in autism in the region with extensive publication by Professor Maureen Samms-Vaughan, Dr. Mohammed Rahbar, and colleagues on possible etiological factors, associations, parental experience, and barriers to diagnoses and implementation of interventions for autism. Dr. Ingrid Van Balkom from the Child and Adolescent Psychiatry Clinic at Oranjestad (Aruba) has also been a major author of published research on autism in our region. They have contributed a wealth of information on potential causation, risk factors, and barriers to diagnoses and implementation of interventions in the Caribbean region.

Legal Issues, Mandates for Service

All of the ten independent countries described in this report and the United Kingdom (of which Anguilla and Tortola are overseas territories) ratified the Convention on the Rights of the Child in the 1990s. Six of the countries (Barbados, Dominica, Grenada, Jamaica, St. Vincent and the Grenadines, and Trinidad and Tobago) ratified the Convention on the Rights of Persons with Disabilities (CRPD) or joined by accession within the

last 10 years with five of the six joining in the last 3 years. The United Kingdom (of which Anguilla and Tortola are dependencies) ratified the CRPD in 1991.

The Bahamas and Jamaica have enacted disability legislation, and with their ratification of the CRPD, many of the other countries are in the process of developing disability legislation. The absence of disability-specific legislation and mandates has decreased the ability of the disabled community to advocate for its needs. The absence of legislation is also reflected in the lack of a structured approach to the provision of services and entitlements for the disabled community. Going forward it is absolutely essential that the organized leadership lobby their respective policy makers to achieve their support for allocating the drafting of specific disability legislation as a high priority in the face of a multitude of competing demands. Enforcement of the legislation in those countries which have enacted relevant laws encounters problems including but not limited to the availability of funding and skilled professionals. In spite of the above-stated challenges, the Dutch overseas territory Aruba has been making strides with the meeting of high-level national officials with representatives of Autism Speaks on September 22, 2014, to assist with the development of an autism strategy on island.

Most countries have stated in their education act the need to provide education for children with special needs in an appropriate environment; however there is no autism-specific legislation or mandates for provision of services or entitlements specifically for autism.

In the region, the receipt of disability assistance is not automatic; the vast majority of persons with disabilities are required to apply for disability assistance. Furthermore in some countries, the financial assistance can be discontinued if the individual is able to earn any income.

Overview of Current Treatments and Centers

Please see below the table of some of the centers that offer evaluation and/or treatment for autism.

Overview of Research Directions

Most of the research published on autism in the region has focused on causation; to this end the University of the West Indies, Mona campus, has led the way with published research in peer-reviewed journals. Their research has examined the possible role of heavy metals (manganese, cadmium, arsenic, and mercury), the role of glutathione S-transferase (*GST*) genes, parental age, factors inhibiting early identification, and intervention.

Dr. Ingrid Van Balkom from the Child and Adolescent Psychiatry Clinic at Oranjestad (Aruba) has also examined and confirmed paternal age as a risk factor and has studied the prevalence rates of autism spectrum disorder in Aruba which has been determined to be 5.3 per 1,000 for the period 1990–1999.

Overview of Training

Awareness training has been the most common type of training that occurs in the Anglophone Caribbean. Public education on autism is often incorporated into Autism month activities. Educational activities on the identification of children with autism targeting healthcare professionals and educators are usually linked to Autism month and Autism Awareness Day. A program of systematic training and continuous education for teachers who work in special education exist in the Bahamas and Tortola; however no systematic continuous education on autism exist for general teachers and healthcare providers in any of the Anglophone countries and territories of the region.

Social Policy and Current Controversies

In general, with increasing visibility and inclusion of persons with disabilities (e.g., in Barbados the leader of the Senate the Honorable Kerry-Ann Ifill is visually impaired, and a major supermarket chain in the region has integrated employees with disabilities in visible positions), attitudes toward persons with developmental disabilities

are improving with slow but steady movement to inclusivity.

Autism awareness continues to grow in the region as a result of continuous advocacy efforts spearheaded by the autism associations, other service organizations, and prominent families affected in the Caribbean region. Additionally, access to the Internet has allowed parents to become acutely aware of the importance of early diagnosis and interventions. In part, this increased knowledge adds to the frustration around accessing intensive, evidence-based intervention in their countries. Parents are often concerned about the quality of the educational services and are fearful that the emphasis of some special needs schools is skewed toward daycare as oppose to learning.

National autism associations exist in 5 of the 12 countries and territories: Bahamas, Barbados, Jamaica, Trinidad and Tobago, and Tortola. The associations are mainly funded by private sector and philanthropic support with some organizations receiving small subventions from the respective governments. These organizations vary in the scope and continuity of services they offer; at minimum, they offer educational information on autism spectrum disorders and support for affected individuals and their families.

The Autism Society of Trinidad and Tobago is one of the more active autism associations in the region with a register of 650 persons with autism. It trains parents as cotherapists and offers social skills play groups for the children. Additionally they provide recreational activities and life skills training for the adults, music and art therapy on Saturdays, and camps for adults and children during the long holidays.

Possibly the area of greatest concern beyond early identification is the plight of young adults with autism. Crisis often occurs when they surpass the age when schooling is mandated by law, and they have not attained skills for independent living or employment. Many parents (often single mothers who are the sole breadwinners of the household) grapple with the choice of leaving their dependent adult son or daughter at home unsupervised or staying away from work at the risk of compromising employment.

In 2015, the deficit of services for dependent children and adults with disabilities was in part addressed in Barbados and Dominica; in Barbados, through the philanthropic work of Derrick Smith, the state-of-the-art vocational center at the Derrick Smith Secondary School and Vocational Centre was opened. The vocational center caters to adults with developmental disabilities. Additionally on the island of Dominica, advocacy by the Parents Advocating for Children with Disabilities Inclusion in Society (PACIS) and an assessment of the number of children affected by disability on the island culminated in the development of the PACIS Care Center scheduled to be opened in September 2015. The center will provide respite for parents who have to make the difficult decision of earning an income outside of the home or caring for the physical needs of their children with disabilities.

ABC

Description

The Autism Behavior Checklist (ABC) is one component of the Autism Screening Instrument for Educational Planning (ASIEP) and is the only one

that has been evaluated psychometrically. The ABC is a 57-item behavior rating scale assessing the behaviors and symptoms of autism for children 3 and older. The instrument consists of a list of 57 questions divided into five categories: (1) sensory, (2) relating, (3) body and object use, (4) language, and (5) social and self-help. Each item has a weighted score ranging from 1 to 4. The ABC is designed to be completed independently by a parent or a teacher familiar with the child for at least 3–6 weeks. It should take from 10 to 20 min to complete. The protocol is then returned to a trained professional for scoring and interpretation.

Historical Background

The Autism Behavior Checklist (ABC) was published in 1980 and is part of a broader tool, the Autism Screening Instrument for Educational Planning (ASIEP). The content of the ABC was based on other autism screening instruments available at the time of its development.

Psychometric Data

The ABC's item score weights and cutoff scores were developed using over 1000 completed questionnaires from children and adults with autism, intellectual disabilities, visual and hearing impairments, and emotional disturbance, as well as those with typical developmental profiles. Higher subtest or total scores reflect greater impairments and more severe levels of autism symptomology.

Although widely used for years, several concerns about its psychometric properties have been identified. For example, studies have found interrater reliability to be much lower than those reported in the initial study during development. In addition, the ABC subscales were not empirically derived and were established by grouping items based on face validity. Later studies have also shown significant differences between parent and teacher reports, although it is not clear whether the discrepancies indicate weaknesses specific to the ABC or reflect differences encountered

commonly when using multiple informants. Perhaps more important are questions concerning the sensitivity and specificity of the ABC. Several studies have suggested the cutoff score of 67 leads to a high number of false negatives. Studies lowering of the cutoff scores to 58 and 45 respectively have shown increased sensitivity and decreased specificity. The ABC has been shown to correlate significantly with the Gilliam Autism Rating Scale (GARS), but correlations with the Childhood Autism Rating Scale (CARS) have been variable.

Clinical Uses

The ABC is primarily designed to identify children with autism within a population of school-age children with severe disabilities. When used in conjunction with other diagnostic instruments and methods, the ABC can be useful as a symptom inventory to be used by clinicians in structuring their evaluation.

Autism Behavior Inventory (ABI)

Abigail Bangerter, Seth Ness and Gahan Pandina
Department of Neuroscience, Janssen Research and Development, LLC, Titusville, NJ, USA

Synonyms

ABI, Autism Behavior Inventory; ABI-S, Autism Behavior Inventory-Short Form

Description

The ABI is a parent- or caregiver-reported outcome measure that was developed to assess change in core and associated symptoms of ASD. The scale consists of 62 items covering 5 domains of behavior. The two core ASD domains are Social Communication (comprised of Reciprocity and Verbal and Nonverbal communication subdomains) and Restrictive Behavior (comprised of Resistance to Change, Restricted Interests, Stereotypical Behavior, Hypersensitivity subdomains). In addition, three associated domains of Mood and Anxiety, Self-Regulation, and Challenging Behavior represent behaviors that are not part of the ASD diagnosis but commonly occur in individuals with ASD and inform clinical consideration. Caregivers endorse items on a 4-point scale relating either to Quality (how *well* behaviors are carried out) or Frequency (how *often* a behavior occurs), over the past 7 days. A shorter version of the ABI (ABI-S), that includes 24 items across all 5 domains, may be used to assess behavior more frequently (e.g., every 2 weeks).

The ABI was developed as an online rating scale, but a paper version is also available. A single form is suitable for caregivers of individuals with ASD aged 3 years through adulthood and may be used with both verbal and minimally verbal groups. Scores are obtained by the averaging of all completed responses for each domain. A core score corresponds to the average of all

responses across the Social Communication and Restrictive Behavior domains.

Historical Background

There are limited reliable, valid, and objective endpoints for measuring clinically and statistically significant changes in the core and associated symptoms of ASD, and this lack hinders the interpretation of treatment outcomes (McConachie et al. 2015). There is a need for measures that have shorter recall periods and reduced burden for respondents, with ample evidence demonstrating that the constructs measured are both relevant and well understood by parents (Aman et al. 2015). The ABI was developed in response to this need, in consultation with regulatory authorities, and in alignment with the FDA (2009) guidelines for patient- and caregiver-reported outcome measures. The iterative scale development of the ABI included two pilot studies (Bangerter et al. 2017), a validation study (Bangerter et al. 2019), and a cognitive interview study (Pandina et al. 2018). Through the entirety of scale development, an initial list of 300 items was refined and reduced through review and testing with multiple stakeholders and based on statistical performance and clinical importance. Caregiver feedback led to the inclusion of additional items on sleep and food sensitivity. Delphi review (Dalkey 1969) by an expert panel of ASD researchers and clinicians led to the selection of items for the ABI-S that were representative across the core and associated domains and were considered to have the most potential for short-term change. Finally, cognitive interviews with caregivers of individuals with ASD, who were representative of a broad range of age and linguistic ability, confirmed that the instructions and items were well understood and that the response options and response period of 1 week were appropriate. Caregivers reported that scale was easy to use and comprehensive in the range of items covered. As a result of this final cognitive debriefing study, a small number of items were removed or reworded resulting in the current 62-item version of the ABI (v1.1) and a 24-item ABI-S (v1.1).

Psychometric Data

Clinical experts assigned ABI items to groups forming domains and subdomains; these were further confirmed with factor analysis in a sample ($n = 353$) of online survey responses (Bangerter et al. 2017). The items were subjected to confirmatory factor analysis (CFA) with principal axis factoring. The Kaiser-Meyer-Olkin measure of the sampling adequacy ratio of total items was 0.932, indicating appropriateness of factor structure. The five factors accounted for 63.74% of the variance in item scores. Items loaded onto respective domains and any cross-loading items were reviewed as part of the item-reduction process. In addition, inter-item correlation, item discrimination, and item information functioning were taken into account to produce a 73-item version of the ABI. This version was further reduced to 62 items comprising the ABI v1.1.

Research in a group of individuals with a clinically confirmed diagnosis of ASD ($n = 144$) demonstrated sound psychometric properties of the ABI v1.1 (Bangerter et al. 2019). Internal consistency across domains was high (Cronbach's α 0.84–0.89). Test-retest reliability 3–5 days after baseline was excellent (ICC values ranging from 0.84 to 0.93). Convergent and discriminant validity were assessed by comparing ABI domain scores with pre-specified subscales of comparison instruments. For convergent validity, strong positive Pearson correlations were found in core ASD domains, for example, ABI Social Communication with Social Responsiveness Scale (SRS), Social Communication and Interaction (0.69), and ABI Restrictive Behavior with Repetitive Behavior Scale-Revised (RBS-R) (0.75). Similarly, for associated domains, ABI Mood and Anxiety correlated with Child and Adolescent Symptom Inventory (CASI) anxiety scale (0.77), ABI Self-Regulation correlated with Aberrant Behavior Checklist (ABC) Hyperactivity and Non-Compliance (0.88), and ABI Challenging Behavior with ABC Irritability (0.76).

Short form items were selected based on their statistical performance and clinical expert feedback. Psychometric properties for the ABI-S v1.1 were similar to those reported for the ABI

v1.1; for example, internal consistency for the ABI-S domains was 0.69–0.79, and test-retest reliability was good (0.77–0.88).

The ABI has been developed as a measure of change in symptoms or behavior over time and is currently being implemented within an interventional clinical trial (NCT03664232), the data from which will allow understanding of the sensitivity to change of the ABI. In an 8–10-week treatment as usual, observational trial (Ness et al. 2019; Bangerter et al. 2019), participants showing improvements in ASD severity based on category change in SRS-2 Total Scores showed analogous ABI domain score improvements in Core ASD Symptoms, Social Communication, and Restrictive Repetitive Behaviors (moderate to large within-group effect sizes of 0.63, 0.50, and 0.41, respectively); these effects were not observed in groups with no documented change or who were reported to have worsened.

Further validation, including sensitivity to change and a confirmatory factor analysis of the ABI v 1.1, is planned as data from ongoing research studies become available. Studies will take place in individuals with broader range of ages and levels of functioning. Translations of the ABI into various languages are also in preparation, alongside associated cross-cultural validation.

Clinical Uses

The ABI and the ABI-S are designed to measure change in response to intervention and allow for the potential to complete one instrument in place of discrete alternatives commonly used in treatment outcome studies and clinical drug trials. Both instruments are freely available in paper form for use in clinical or research settings, subject to terms and conditions, and can be obtained via email at autismbehaviorinventory@its.jnj.com.

Caregivers, including healthcare professionals who spend more than 3–4 h a week with the person who has ASD, can complete the scale. The scale can be repeated at weekly or longer intervals by the same respondent, in order to determine response to an intervention based on

change from baseline administration. The ABI takes approximately 10–20 min to complete and the ABI-S around 5–10 min.

A clinician version of the ABI (ABI-C) is currently being tested. This version allows clinicians and other healthcare professionals to assess the same domains and subdomains of the ABI, using 14 items with a 0–7-point scale of symptom severity.

Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act of 2019 (Also Referred to as the “Autism CARES Act of 2019”)

Annemarie M. Kelly and Christina N. Marsack-Topolewski

College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

The “Autism Collaboration, Accountability, Research, Education, and Support Act of 2019,” abbreviated as the “Autism CARES Act of 2019” (hereafter “the Act”), is a milestone law in the United States that provides federal funding to the US Department of Health and Human Services (DHHS) for services and research concerning individuals with autism spectrum disorder (ASD) (Pub. L. No. 116–60, 2019).

The Act supports ASD-related programs in three DHHS agencies: National Institutes of Health (NIH), Centers for Disease Control and Prevention (CDC), and Health Resources and Services Administration (HRSA) (DHHS 2017). The programs covered under the Act include biomedical ASD research and the continued development of best practices to enhance the lives of persons with ASD. Importantly, the Act also formally expands the focus of US government programs to include research and services that assist individuals with ASD across their life spans, not only children and young adults (Turcotte et al. 2016).

Legislative Details

Under the Act, the US Congress assigns government funds for a wide range of ASD-related programs with an emphasis on seven key activities: research, surveillance, early detection, prevention, treatment, education, and disability support. The Act has three general goals:

[1] The law expands efforts to conduct research, surveillance, education, detection, and intervention for all individuals with autism spectrum disorder across their lifespan, regardless of age...

[2] [It] also aims to reduce disparities among individuals from diverse racial, ethnic, geographic, or linguistic backgrounds, and [3] directs additional care to rural and underserved areas. (U.S. House of Representatives 2019)

The Act defines “underserved areas” as geographic locations where there are shortages of healthcare professionals available to provide services to the public. In addition, the Act re-establishes the Interagency Autism Coordinating Committee (IACC) federal advisory committee, which is responsible for coordinating and guiding government efforts on issues related to ASD in public forums (IACC 2001–2020). The IACC is made up of federal government workers, industry experts, academic researchers, and members of the public.

The Act’s 5-year reauthorization of funds includes annual authorizations of \$23.1 million for developmental disability surveillance and research; \$50.599 million for ASD education, early detection, and intervention; and \$296 million to carry out the work of the IACC and other DHHS programs. The Act’s funding covers activities through September 30, 2024. Congress will need to provide additional government funding before October 1, 2024, so that the DHHS can continue the services and research facilitated under the Act.

The Autism CARES Act of 2019 is designed to help society obtain new insights regarding effective ASD services, interventions, and treatments (U.S. House of Representatives Congressman Chris Smith 2019). The Act contains eight primary components:

1. Authorizes \$1.8 billion in funds, including \$296 million in annual funding to the NIH

- (2020), \$23.1 million to the CDC (2019), and \$50 million to HRSA (2019)
2. Reauthorizes and expands the IACC
 3. Reauthorizes government program activities including:
 - (a) Expanding ASD research at the NIH (2015)
 - (b) Continuing the CDC’s collection of state-level ASD data (CDC 2020)
 - (c) Continuing the ASD education, early detection, and intervention activities supported by the HRSA and the IACC (HRSA 2020)
 4. Revises the scope of government programs and activities in three key areas:
 - (a) Encompassing ASD individuals of all ages, rather than only children
 - (b) Increasing funding on programs in areas with a shortage of personal health services
 - (c) Reducing health-outcome disparities across diverse populations.
 5. Adds new members of IACC from the Departments of Labor, Justice, Veterans Affairs, and Housing and Urban Development.
 6. Increases from two to three IACC members who are self-advocates, parents or legal guardians and advocacy/service organizations.
 7. Empowers the DHHS Secretary to prioritize grants to rural and underserved areas across the United States
 8. Requires DHHS agencies to compile a comprehensive report to Congress that details current and future outlooks government services and research initiatives concerning ASD. This report must be completed by no later than September 30, 2021, which is 2 years after

the law was first enacted. The Act specifies that the report must contain the following information:

- (a) Demographic factors associated with the health and well-being of individuals with ASD
- (b) Recommendations on establishing best practices to ensure interdisciplinary coordination
- (c) Improvements for health outcomes
- (d) Community-based behavioral support and interventions
- (e) Nutrition, recreational, and social activities
- (f) Personal safety

Legislative History and Background

Congress typically approves funds for DHHS’ ASD-related programs in 5-year appointments. For the past two decades, Congress has continuously recognized the need for the IACC and for increased US government research and support programs regarding ASD. See Table 1. In 2000, Congress first established the IACC under the Children’s Health Act of 2000 – this law intensified US government research, prevention, and treatment activities for a number of conditions that significantly impact children, including ASD (Pub. L. No. 106–310, 2000). In 2006, Congress passed the Combating Autism Act of 2006, which focused on specific DHHS services for populations with ASD and elevated the status of the IACC as an official federal advisory committee that communicates directly with the Office of the Secretary of DHHS (Pub. L. No. 109–416, 2006).

Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act of 2019 (Also Referred to as the “Autism CARES Act of 2019”),

Table 1 Timeline of key federal legislation to support ASD-related government programs: 5-year reauthorization cycles from 2000 to 2019

Year	Law title	Public law number
2000	Children’s Health Act	Public Law 106–310
2006	Combating Autism Act	Public Law 109–416
2011	Combating Autism Reauthorization Act	Public Law 112–32
2014	Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act	Public Law 113–157
2019	Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act	Public Law 116–60

From 2006 to the present, Congress has reauthorized funding for the IACC and steadily expanded funding for ASD-related programs within DHHS. Each act focuses on supporting federal ASD research and services for surveillance, early detection, prevention, treatment, education, and disability programs within DHHS. In 2011, 2014, and 2019, Congress passed the following respective laws: Combating Autism Reauthorization Act of 2011 (Pub. L. No. 112–32, 2011); Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act of 2014 (Pub. L. No. 112–32, 2014); and the Autism Collaboration, Accountability, Research, Education, and Support (CARES) Act of 2019 (Pub. L. No. 116–60, 2019).

On February 7, 2019, the Act was first introduced as a bill within the House of Representatives (House Bill 1058). The House passed the Act on July 24, 2019. The Senate approved it shortly thereafter on September 19, 2019. On September 30, 2019, the Act was signed into law by the president. More than 35 nonprofit organizations endorsed the Act, including the Autism Society of America, Autism Speaks, Autism New Jersey, the Association of University Centers on Disabilities, the Children’s Hospital Association, the National Council on Severe Autism, the Congress, and the National Down Syndrome Society.

Autism Cymru

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Major Areas or Mission Statement

Autism Cymru is Wales's pioneering national charity for Wales. It is a practitioner-led charity set up in 2001 to improve the lives of people in

Wales with an autistic spectrum disorder and their families. It has a dedicated national brief in Wales and in the projection of Welsh practice within and outside Wales. Autism Cymru takes the view that everyone with an autistic spectrum disorder in Wales should receive a service appropriate to their assessed needs, whatever their age and wherever they live. In order to achieve this, Autism Cymru actively promotes at both national and local levels the practice of strategic, collaborative, and multidisciplinary partnerships and highly focused coordination of services to people with autistic spectrum disorders and their families. Autism Cymru's primary task was successfully to influence the Welsh Assembly Government to establish the world's first government-led strategy for autism, which was launched at Autism Cymru's third International Autism Conference in Cardiff in April 2008. Autism Cymru's Chief Executive, Hugh Morgan OBE, heads up the implementation of the Assembly Government's Action Plan for Autism.

Landmark Contributions

Wales is the only country in the world with a national strategy for autism.

Major Activities

Autism Cymru runs the pioneering bilingual websites, Awares (www.awares.org). Every November, Autism Cymru's editor, Adam Feinstein, runs the Awares international online autism conference (www.awares.org/conferences), the largest event of its kind in the world, with more than 60 world autism experts taking part, along with thousands of delegates. Professor Simon Baron-Cohen has called this event "the finest online conference on the planet." Autism Cymru together with Autism Northern Ireland, Scottish Society for Autism, and the Irish Society for Autism has launched the Celtic Nations Autism Partnership. This will lead to shared opportunities for joint working in Northern Ireland, Scotland,

and Republic of Ireland, in addition to Autism Cymru's existing work in Wales.

Autism Cymru carries out research in partnerships with universities in Wales. In 2010, Professor Sue Leekam became the first chair of autism at Cardiff University and head of the new Welsh Autism Research Centre, based at the university's school of psychology and supported by Autism Cymru. Autism Cymru works in partnership with Mudiad Ysgolian Meithrin with funding from Children in Need to train Welsh medium playgroup leaders across Wales. Autism Cymru works in partnership with Autism Northern Ireland (PAPA) on UK and European campaigns to improve the lives of those with autism and to project best practice in each country. Autism Cymru works with local authorities and local health boards to develop local strategies for autism. Autism Cymru works with local education authorities in Wales to deliver its Inclusive Schools and ASDs: Whole School Training and Research Project. Autism Cymru works in partnership with the North Wales Police and Dyfed Powys Police to operate the Emergency Services ASD Attention Card Scheme which raises awareness of autism among members of the emergency services in Wales.

Autism Cymru has worked with Bro Morgannwg NHS Trust on a research project connected to the criminal justice system. Autism Cymru operates the AWARES EDUNET website and School Fora for education professionals. Autism Cymru publishes books and bilingual information booklets for professionals, parents, and people with autism. Publications include *All About Autistic Spectrum Disorders* and *My Brother Gwern*, a book for siblings of children with autism which won an award at Welsh Language in Healthcare Awards 2006. Autism Cymru's work also takes place on an international stage and with European partners, including Autism-Europe. For example, its 2009–2012 European-funded *Deis Cyfle* project (Opportunities for people with autism in education and employment) reached out to over 5,700 people across Wales and Ireland. The charity is also the sole national autism charity governed by those living in Wales. Autism Cymru's Chair is Professor Bill Fraser CBE. Its Patron is Lord Dafydd Wigley and its President is Dame Stephanie Shirley.

Description

The Autism Diagnostic Interview-Revised (ADI-R; Le Couteur et al. 2003; Lord et al. 1994) is a standardized, semistructured, investigator-based interview administered by trained clinicians to parents or caregivers of individuals referred for a possible autism spectrum disorder (ASD). The ADI-R includes 93 items in three domains of functioning: communication; reciprocal social interactions; and restricted, repetitive, and stereotyped patterns of behavior, as well as other aspects of behaviors. All items in the ADI-R are coded for current and past behavior. Current refers to whether the behavior has occurred in the past 3 months. For some items, "past" refers to whether the behavior "ever" occurred, whereas others ask whether the behavior was present during a specifically defined period between 4 and 5 years of age (referred to as "most abnormal 4 to 5").

Up to 42 of the interview items are systematically combined to produce a formal, diagnostic algorithm for autism based on the ICD-10 (World Health Organization [WHO] 1990) and DSM-IV (American Psychiatric Association [APA] 1994) criteria as specified by the authors. In addition to the three domains of behavior, there is a fourth domain, *abnormality of development evident at or before 36 months*, to indicate whether the child meets criteria for age of onset. Each domain has a cutoff; a child must meet or exceed cutoffs in all four areas to receive an ADI-R classification of “autism.” Separate cutoffs are available for the communication domain, depending on whether or not the child is verbal (defined as showing “functional use of spontaneous, echoed, or stereotyped language that, on a daily basis involves phrases of three words or more that at least sometimes include a verb and are comprehensible to other people,” a score of 0 on item 30 *overall level of language*). Other criteria including using lower cutoffs with the same set of items have been used to create an algorithm for broader classification of autism spectrum disorders (ASD) as in several collaborative studies (Dawson et al. 2004; Lainhart et al. 2006; Risi et al. 2006). The diagnostic algorithm for children 4 years old and above is based on the “ever/most abnormal” codes, but current behavior algorithm forms are available to facilitate a clinical diagnosis for children from 2 years old and above.

A toddler version of the ADI-R was also developed several years ago to provide descriptive data for research with children under 4 years of age. The Toddler ADI-R has a total of 125 items, including 32 new questions and codes about the onset of autism symptoms and general development. Other items are identical to the ADI-R, with the exception that the Toddler ADI-R does not have codes for behaviors between 4 and 5 years of age.

Previous analyses suggested that the diagnostic algorithm was useful for children with a nonverbal mental age above 2 years (Le Couteur et al. 1989; Lord et al. 1994; Rutter et al. 2003). Thus, the interview had been appropriate for the diagnostic assessment of any person within the age range extending from early childhood to adult life,

provided that they have a nonverbal mental age above 2 years. Recently, however, newly developed algorithms for toddlers and young preschoolers have shown improved predictive validity compared to the preexisting algorithms for young children from 12 to 47 months of age (Kim and Lord 2011). These algorithms extend the use of the ADI-R to children as young as 12 months and a nonverbal developmental level of at least 10 months. In addition, these new algorithms include items present in both the toddler and standard versions of the ADI-R, allowing for use of the algorithms with either version.

Most items in the ADI-R relate to behaviors that are rare in individuals who do not have ASD and/or who do not have profound intellectual disabilities. Thus, numerical estimates of the scores of typically developing children based on general population have not been obtained. However, there have been several comparisons to children and adolescents with other disorders, which have been used in the development of the diagnostic algorithms (Le Couteur et al. 1989; Lord et al. 1994; Kim and Lord 2011). Researchers have used individual domain scores or an overall total of the three domains as estimates of autistic symptom severity, though the validity of this approach has not been directly tested. Scores have been published for many research populations but not yet systematically dimensionalized.

Historical Background

The ADI was first developed in 1989 (Le Couteur et al. 1989), which was modified in 1994 (Lord et al. 1994). The 1994 version was somewhat shorter than the original in order to make the interview more feasible in both clinical and research settings. The current version of the ADI-R was published in 2003 by Western Psychological Services.

The development of the toddler version of the ADI-R was completed in 2006 for research purposes. Following the development of the toddler version of the ADI-R, there was an increase in demand for diagnostic instruments for very young children, which prompted the development of the

new diagnostic algorithms for toddlers and young preschoolers (Kim and Lord 2011). The final algorithms for toddlers and young preschoolers contain fewer items than the original algorithms and are appropriate for use with children 12–47 months of age.

Psychometric Data

Psychometric properties for the original ADI were reported for a sample of 16 children and adults with autism and 16 children and adults with intellectual disabilities; each group included individuals that spanned wide ranges of age and performance IQ (with a mean age of 12.28 years and a standard deviation of 3.43 from a performance IQ of 43 to 71). Participants were carefully selected and blindly interviewed and coded. Interrater reliability was assessed, with multirater kappas ranging from 0.25 to 1 for each item. Intraclass correlations were above 0.94 for all subdomain and domain scores. The majority of individual items showed good discriminative validity between the autism group and the group of individuals with nonautism intellectual disabilities (Le Couteur et al. 1989).

Psychometric properties for the development of the algorithms for the current ADI-R were based on a sample of 25 children with autism and 25 children with intellectual disabilities who were carefully selected and blindly interviewed and coded (Lord et al. 1994; Rutter et al. 2003). These children ranged in chronological age from 36 to 59 months, with nonverbal mental ages ranging from 21 to 74 months. Using a sample of 10 children, interrater reliability was assessed; multirater kappas ranged from 0.63 to 0.89 for each item. Using the same sample, intraclass correlations were above 0.92 for all subdomain and domain scores. In addition, after the initial standardization of the ADI-R in 1989, a separate sample of 53 children with autism and 41 nonautistic children with intellectual disabilities or language impairments was used to further assess the validity of the ADI-R (Lord et al. 1993). The results of the study showed that the interrater reliability was as high as the initial study, with multirater kappas

ranging from 0.62 to 0.96 for individual items. Test-retest reliability was also very high, with all coefficients in the 0.93–0.97 range.

The majority of individual items in the current ADI-R showed good discriminative validity between children with autism and children with intellectual disabilities (see Lord et al. 1994). The existing algorithms differentiated children with autism over 36 months of age from children with nonspectrum disorders, showing high sensitivity and specificity (both over 0.90). Further analyses of data from preschool children revealed that the ADI-R algorithms differentiated children over 2 years with ASD from those with other developmental disorders. However, for children under 2 years, discrimination between nonverbal children with ASD and nonverbal children without ASD was poor, resulting in low specificity, especially for children with mental ages under 18 months, (Lord et al. 1993).

In a more recent study including a larger sample (Risi et al. 2006), the ADI-R showed high sensitivity (above 80%) for children with ASD under 3 years of age, but lower specificity for the comparison of nonautism ASD versus nonspectrum disorders (around 70%). Ventola et al. (2006) reported that, for children between 16 and 37 months of age, the diagnostic classifications made based upon the ADI-R algorithm resulted in lower sensitivity than those made using the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 1999), Childhood Autism Rating Scale (CARS; Schopler et al. 1980), or clinical judgment using the DSM-IV criteria. Wiggins and Robins (2008) also found that ADI-R algorithms resulted in poor sensitivity for children in the same age range when the standard cutoff for the RRB domain was included in the diagnostic criteria. Given the low sensitivities and specificities being reported for young children, new ADI-R algorithms were developed for toddlers and preschoolers between 12 and 47 months of age using a sample of 491 children with ASD, 136 with nonspectrum disorders (NS), and 67 with typical development (Kim and Lord 2011). The new ADI-R algorithms consist of two different cutoff scores: one for research (more restrictive, higher specificity with lower

sensitivity) and one for clinical purposes (more inclusive, higher sensitivity with lower specificity). They also include “ranges of concern” for clinical use (discussed below). In this sample, sensitivity using the clinical cutoff ranged from 80% to 94% and specificity ranged from 70% to 81% for the comparison of nonautism ASD vs. NS. Using the research cutoffs, the comparison of nonautism ASD vs. NS resulted in sensitivity ranging from 80% to 84% and specificity ranging from 85% to 90%. Another multi-site study (Kim et al. 2013) using two independent datasets provided by National Institute of Health funded consortia, the Collaborative Programs for Excellence in Autism, and Studies to Advance Autism Research and Treatment ($n = 641$) and the National Institute of Mental Health ($n = 167$) replicated the results from the original psychometric study, including the diagnostic validity and factor structure of the new algorithms for toddlers and young preschoolers (Kim and Lord 2011). Results suggested that the new ADI-R algorithms can be appropriately applied to existing research databases with children from 12 to 47 months and down to nonverbal mental ages of 10 months for diagnostic grouping. With a non-US sample, sensitivities, especially for those with phrase speech, were lower, using the new algorithms for toddlers and young preschoolers, suggesting that the algorithms need to be replicated more with other independent, non-US samples (de Bildt et al. 2015).

Clinical Uses

The ADI-R offers a profile of a child, adolescent, or adult which includes information regarding reciprocal social interactions, language and communication, and restricted, repetitive, and stereotyped behaviors and interests. Items are scored based on caregivers’ detailed descriptions of the history and behaviors of their child, thus allowing the clinician to gather both quantitative and qualitative information. One important caveat for clinical users to recognize is that diagnostic classifications based on the algorithms and true clinical diagnoses are not the same. Clinical diagnosis is based on multiple sources of information,

including direct observations (Le Couteur et al. 2007; Risi et al. 2006; Kim and Lord 2012). Risi et al. (2006) found a better balance of sensitivity and specificity when the ADI-R and the ADOS were used in combination compared to when each instrument was used alone. The combined use of these instruments resulted in sensitivity and specificity of 82% and 86%, respectively, for children with autism compared to children with non-spectrum disorders over age 3 years. For younger children, sensitivity and specificity for the same diagnostic comparison using both instruments were 81% and 87%, respectively. In contrast, when each instrument was used alone, specificities ranged from 59% to 72%. Le Couteur and her colleagues (2007) also examined the combined use of the ADOS and ADI-R for preschoolers with ASD using revised ADOS algorithms (Gotham et al. 2007). Consistent with Risi’s 2006 study, the authors found that combining information from both ADOS and ADI-R provided improved diagnostic accuracy compared to either instrument in isolation. Similarly, using the newly developed ADI-R algorithms for toddlers and young preschoolers and the revised ADOS and new ADOS-Toddler algorithms, Kim and Lord (2011) also found that for very young children, the combined use of the ADOS and ADI-R improved diagnostic validity compared to when each instrument was used alone. Thus, even though the ADI-R provides information about the individual’s history and description of his or her current functioning from a broad range of contexts, the ADI-R alone cannot be used to make a clinical diagnosis.

The diagnostic algorithm cutoffs allow classification of ASD based on patterns of behavior, meeting the current DSM-IV or ICD-10 diagnostic criteria for autistic disorder. In addition to single cutoff scores, the new algorithms for toddlers and young preschoolers provide clinicians and researchers with several different options for the diagnostic classification of young children. For clinical purposes, ranges of concern (little-to-no concern, mild-to-moderate concern, and moderate-to-severe concern) that represent the severity of autism symptoms in young children are also provided. A clinician or a researcher can

use these ranges of concern to inform decisions about whether or not a child should be followed up with further assessments or should be quickly referred for treatment services irrespective of diagnostic cutoffs. Scores that fall in the little-to-no range of concern indicate that the child is reported to have no more behaviors associated with ASD than children in the same age range who do not have ASD. On the contrary, a child who scores in the mild-to-moderate range has a number of behaviors consistent with, but perhaps not unique to, ASD. For clinical purposes, children in the mild-to-moderate or moderate-to-severe ranges of concern should receive further evaluation and follow-up, including other cognitive and language assessments, and recommendations for treatment. In addition to ranges of concern, single cutoff score can be used when more strictly stratified groupings are necessary, such as for intervention, neuroimaging, or genetic research. These different alternatives allow clinicians and researchers to be transparent about the choices they make, recognizing that diagnostic decisions about ASD in very young children are less stable and precise than for older children and adolescents.

In addition to the diagnostic algorithms, the ADI-R includes a current behavior algorithm form that can be used in clinical settings to assess changes that occur during or after interventions or that may reflect increasing developmental maturity or changing life circumstances. Because the current behavior algorithm form has not been empirically validated, it is not intended to be used as a diagnostic algorithm. The development of a new algorithm is underway by the authors in anticipation of an updated protocol and algorithm with new criteria. A shorter version of the ADI-R that can be used over the phone is also in the process of being developed and validated.

The ADI-R provides a useful structure to obtain history and understand a caregiver's perspective on his or her child's symptoms associated with ASD. However, it requires substantial practice to administer reliably, and it takes approximately 2–3 h to administer. The ADI-R should only be used by appropriately experienced clinicians who are familiar with ASD and relevant behaviors. Training workshops and videotapes are available to help clinicians and researchers

understand the scoring and administration of the ADI-R. For research use, interviewers must meet standards for reliability.

In a recent effort to identify children with ASD more efficiently, a brief parent interview, Autism Symptom Interview (ASI; 15–20 min), has been designed primarily as a case confirmation tool for ASD (Bishop et al. 2017). The ASI has been based on questions from the ADI-R. Based on school-age children ranging from 5–12 years of age, the verbal algorithm yielded a sensitivity of 0.87 (95% CI = 0.81–0.92) and a specificity of 0.62 (95% CI = 0.53–0.70). When used in conjunction with the ADOS, sensitivity and specificity were 0.82 (95% CI = 0.74–0.88) and 0.92 (95% CI = 0.86–0.96), respectively. Internal consistency and test-retest reliability were both excellent. Based on these results, the authors have concluded that particularly for verbal school age children, the ASI may serve as a useful tool to more quickly ascertain or classify children with ASD for research or clinical triaging purposes. Additional data collection is underway to determine the utility of the ASI in children who are younger and/or nonverbal.

ADOS

Description

The Autism Diagnostic Observation Schedule (ADOS) is a semi-structured observation scale designed to observe social behavior and communication in children and adults referred for possible diagnosis of autism spectrum disorder (ASD). Originally developed as a research instrument, it became commercially available through Western Psychological Services in 2001 (Lord et al. 1999) and is used widely in clinical, school, community, and research settings. The goal of the ADOS is twofold: to help clinicians and researchers discriminate autism from other disorders and

typically developing individuals and to characterize social and communicative behaviors associated with autism (Lord et al. 1989). It is often used in conjunction with the Autism Diagnostic Interview-Revised (ADI-R; Rutter et al. 2003), a parent interview. When used by a skilled clinician, together, these two instruments form the “gold standard” for the diagnosis of ASD.

The format of the ADOS is unique. It is a structured interaction between an examiner and individual in which the examiner’s behavior is standardized using a hierarchy of structured and unstructured social behaviors. The examiner creates a “social world” in which occasions for specific behaviors are purposefully orchestrated in order to observe the presence – or absence – of an expected response. For example, with an older child or adult with fluent language, the examiner might initiate a conversation and observe whether the individual participates in a reciprocal exchange or asks about the examiner’s experiences. With a child or adolescent with limited language, the examiner might observe whether the individual conveys shared enjoyment in an activity, such as bubble play, by smiling, laughing, or requesting for the activity to continue. The ADOS goes beyond measuring the frequency of behaviors and also focuses on the *quality* of social behavior, allowing the examiner to make informed decisions regarding the presence of features associated with a diagnosis of ASD. Because of the movement between structured and unstructured tasks, and the need for keen observation within such tasks, it is imperative the ADOS is administered by a skilled examiner familiar with ASD.

The original version of the ADOS (Lord et al. 2000) consists of four modules based on age and language level, with “higher” modules generally requiring more language and social demands. Each module takes approximately 35–60 min to administer. Module 1 is for individuals with a minimum of no speech or the emergence of simple phrases. Module 2 is designed for individuals who use flexible three-word phrases, but are not yet speaking fluently. Modules 3 and 4 are for individuals with fluent speech. For the purposes of the ADOS, three-word phrases are defined as “regular

spontaneous meaningful use of three-word utterances including a verb,” while fluent speech is defined as “producing a range of flexible sentence types, providing language behavior the immediate context and describing logical connections within a sentence” (Lord et al. 1999).

Though each module of the ADOS has different language requirements, the overall format and structure is the same. In fact, there is considerable overlap of tasks across modules. In each module, the examiner interacts with the individual, administering a series of tasks, or “presses” for particular social behaviors. Modules 1 and 2 are conducted while moving around a room and include play-based tasks appropriate for young children or individuals with very limited language. Modules 3 and 4 generally take place while sitting at a table and include tasks involving more conversation.

Immediately after the administration of all tasks, the examiner rates the individual’s behavior on items across domains including communication, social interaction, play or imagination, and stereotyped behaviors and restricted interests. Ratings, or codes, are made on an ordinal scale from 0 to 3, with 0 indicating no evidence of abnormality related to autism and 3 indicating definite evidence, such that behavior interferes with interaction. Selected items from each domain are used to generate a diagnostic algorithm. These items were selected for their ability to discriminate between ASD and nonspectrum disorders and also for their relevance to DSM-IV and ICD-10 criteria. A classification of autism or non-autism ASD is made when thresholds on the social affect and restricted and repetitive behavior domains, and a combined social affect and restricted and repetitive behavior total, are exceeded. When combined with information from other sources, including but not limited to a parent interview and clinical judgment, an ADOS classification of autism or ASD may lead to a diagnosis on the spectrum.

Since its publication by WPS in 1999, the ADOS has expanded considerably. Revised algorithms for modules 1–3 were developed to improve the instrument’s sensitivity and specificity (Gotham et al. 2007), and a toddler module appropriate for children under 30 months old has

been available for research purposes (Luyster et al. 2009). The revised ADOS algorithms and the new toddler module were released commercially by WPS in 2012 in the second edition of the ADOS (ADOS-2; Lord et al. 2012a, b) (see Table 1 for a summary of ADOS algorithms). Adapted versions of modules 1 and 2 with modified tasks and materials are in development for adolescents and adults with limited language (Hus et al. 2011). The ADOS-Change (ADOS-C; Colombi et al. 2011), a measure using ADOS item descriptions with expanded codes ranging from 0 to 5, has also been created. This measure is scored by watching an unstructured interaction between an adult and child and will be used to measure response to intervention in young children.

Historical Background

The first version of the ADOS was developed primarily as a diagnostic research tool. Direct observation, in addition to observations in familiar settings and parent interviews, was an important part of diagnostic assessment, but such observations were not conducted in a standardized fashion across clinicians or patient. Furthermore, researchers needed a method in which to examine features specific to autism, such as impairments in social interaction and communication, independent of those accounted for by intellectual disability. A series of publications highlight the development of the ADOS from its first version to the significantly expanded versions in use today (Table 2).

The first ADOS (Lord et al. 1989) was intended for individuals between five and 12 years old, with an expressive language level of at least three years. It included only eight tasks, with two sets of materials based on developmental level and chronological age. The validation sample included 20 children and adolescents with autism and 20 children with intellectual disability matched for chronological age, verbal IQ, and gender. The measure showed promise in distinguishing children with autism from those with intellectual disability.

As public awareness of autism increased and more younger and nonverbal children were referred to clinics for diagnostic evaluations, there became a need to develop a “downward extension” of the ADOS that would be appropriate for younger children with no-phrase speech. The Pre-Linguistic Autism Diagnostic Observation Schedule (PL-ADOS; DiLavore and Lord 1995) was intended for children less than 6 years old with limited language. It included 12 tasks with 31 overall ratings. All tasks were administered in the context of play and were informed by the increasing amount of research on early indicators of autism, particularly those studies focusing on joint attention, functional and symbolic play, imitation, and early patterns of language development. The PL-ADOS was validated on a sample of 63 children with autism or developmental delay and matched for chronological age or language level. Overall, the algorithm was successful at differentiating autism from developmental delay, but its performance was not as good when discriminating verbal children with autism from nonverbal children with developmental delay, and children with autism who had some expressive language tended to be underclassified by the instrument.

The ADOS-Generic (ADOS-G; Lord et al. 2000) was developed directly from its original version (Lord et al. 1989) and the PL-ADOS (DiLavore and Lord 1995). It aimed to improve the tendencies to overdiagnose autism in children with insufficient language ability and underdiagnose children with higher language abilities. Furthermore, it sought to extend the current tasks to be appropriate for adolescents and adults. The ADOS-G differed from its predecessors in that it spanned a broader developmental and age range and was the first to introduce the use of modules across different developmental and language levels. It was also the first version to provide continuous scores from ASD to autism, thus making it applicable for children with broader ranges of social and communication impairments.

The ADOS-G was normed on a sample of 381 children, adolescents, and adults spanning a broader diversity of spectrum and nonspectrum disorders. The sample included a group of

Publication	Contribution
Autism Diagnostic Observation Schedule: A Standardized Observation of Communicative and Social Behavior (Lord et al. 1989)	First published version of the ADOS
The Pre-Linguistic Autism Diagnostic Observation Schedule (DiLavore and Lord 1995)	Introduction of alternate version of ADOS more appropriate for individuals with very limited language
The Autism Diagnostic Observation Schedule-Generic: A Standard Measure of Social and Communication Deficits Associated with the Spectrum of Autism (Lord et al. 2000)	Consolidation of ADOS and PL-ADOS Introduction of four module structure Appropriate for broader range of social communication deficits and age Accompanied by commercial release of ADOS by Western Psychological Services (Lord et al. 1999)
The Autism Diagnostic Observation Schedule: Revised Algorithms for Improved Diagnostic Validity (Gotham et al. 2007)	Revised algorithms for improved diagnostic validity Algorithms grouped by developmental and language ability Inclusion of restricted and repetitive behaviors in algorithm totals
The Autism Diagnostic Observation Schedule-Toddler Module: A New Module of a Standardized Diagnostic Measure for Autism Spectrum Disorders (Luyster et al. 2009)	Introduction of ADOS-Toddler Appropriate for use in children under 30 months with mental age of at least 12 months
Standardizing ADOS Scores for Measure of Severity in Autism Spectrum Disorders (Gotham et al. 2009)	Created standardized severity metric to measure change in ADOS assessments over time, age, and module

individuals diagnosed with autism, PDD-NOS, and a group designated as “nonspectrum,” which included individuals with diagnoses of mental retardation, language disorder, attention-deficit/hyperactivity disorder, oppositional defiant disorder, anxiety, depression, and obsessive-compulsive disorder and children who were typically developing. The ADOS-G algorithms were successful at discriminating ASD from nonspectrum, but were not as good at making distinctions between children with milder forms of ASD. Upon WPS publication of the ADOS-G in 1999, the “G” was dropped and the instrument became solely known as the ADOS. Gotham et al. (2007) and colleagues sought to improve the diagnostic validity of the ADOS by validating revised algorithms for modules 1–3 on a significantly larger sample of children with ASD and nonspectrum diagnoses. The new algorithms were grouped into developmental cells to reduce the effects of age and IQ and included more similar items across modules with the same number of items per algorithm to increase comparability. Factor analyses yielded two domains representing features of social affect and restricted and repetitive behaviors (RRBs);

thus, the new algorithms required thresholds to be met in social affect, RRB, and a combined total, in order to meet classification criteria for autism or ASD. This was a significant departure from earlier versions of the ADOS in which RRBs were not included on the algorithm and social interaction and communication were considered separately. Specificity in children with nonverbal mental ages of 15 months and younger continued to pose problems in distinguishing children with ASD from those with other language-based disorders or intellectual disability. Since the publication of the revised algorithms, however, several replications with larger and more diverse samples have been conducted with consistent results supporting the improved diagnostic validity of the new algorithms.

Though higher scores on the ADOS do indicate a greater number of behaviors consistent with core deficits of ASD and, to some degree, greater severity of impairment, ADOS scores were not standardized for this purpose. The creation of revised algorithms paved the way for the development of calibrated severity scores (Gotham et al. 2009). Severity scores that reduced the

effects of IQ and chronological age were developed to promote the comparison of ADOS assessments over time, age, and module and to identify trajectories of autism severity. Raw scores have been mapped onto a 10-point severity metric with lower scores indicating less autism impairment.

As calibrated severity scores were being developed, a new module of the ADOS, the ADOS-Toddler, was also underway. Advancements in the understanding of autism in very young children, particularly infants and toddlers, increased the need for diagnostic tools appropriate for use in that developmental level. Because the ADOS, even with revised algorithms, had limited applicability for children with nonverbal mental ages below 15 months, the toddler module was created. The toddler module consists of a combination of ADOS and some new tasks and is intended for use in children 12–30 months chronological age, with nonverbal mental ages of at least 12 months, and who are walking independently. It includes two algorithms, nonverbal 12–20 months/12–30 months and verbal 21–30 months. Because of the relative instability of diagnostic classifications in very young children, the toddler algorithms differ from those of the ADOS-G in two ways. First, they yield research classifications of ASD or nonspectrum and do not make distinctions between autism and ASD, and second, they provide clinical “ranges of concern,” (little-to-no, mild-to-moderate, and moderate-to-severe concern for ASD) indicating the degree of need for continued clinical monitoring.

The ADOS has developed considerably since the first 1989 version, and research on expanded applications of the instrument continues today. Continued testing of the ADOS is occurring in clinical and community-based settings, in addition to the application of translated versions for use in languages other than English.

Psychometric Data

Reliability. Across all ADOS modules, intraclass correlations for the social, communication, social communication, and restricted and repetitive domains were 0.93, 0.84, 0.92, and 0.82, respectively, and mean weighted kappas across items ranged from 0.65 to 0.78. Test-retest reliability ranged from 0.59 to 0.82. For the toddler module, intraclass correlation was 0.96 for the entire protocol and mean weighted kappa was 0.67. Test-retest reliability was 0.86 for the 12–20/21–30 nonverbal algorithm and 0.95 for verbal 21–30. Interrater reliability across all modules is reported in Table 3.

Diagnostic validity. Algorithm cutoffs for the ADOS were excellent for autism and ASD relative to nonspectrum disorders, with even greater performance with the introduction of revised algorithms. Algorithm cutoffs for the toddler module yielded high sensitivity and specificity. Sensitivities and specificities for current and revised algorithms of the ADOS are reported in Tables 4 and 5 and in Table 6 for the toddler module algorithms.

Clinical Uses

The ADOS is intended for use by clinicians familiar with autism. Valid administration and interpretation of results is dependent on the clinical skill of the examiner and requires substantial training. The ADOS can be used clinically upon completion of a two-day WPS-certified clinical course or from WPS training DVDs. Even with training, however, administration of the ADOS should not be attempted without significant practice in administering the tasks, in observing features of autism as specified by the ADOS items, and in

scoring. For those using the ADOS in research settings, more rigorous requirements for use exist. Individuals must attend a standardized training workshop and then obtain reliability with workshop leaders and within the research site. As

specified in Lord et al. (2000), research reliability is defined as agreement of 80% or above on ADOS protocols and algorithms on three consecutive scorings for modules 1 and 2 and modules 3 and 4, separately.

Autism Diagnostic Observation Schedule, Table 6 Sensitivities and specificities for toddler module algorithms: ASD versus nonspectrum (Luyster et al. 2009)

<i>N</i> = 234	Se	Sp
12–20/nonverbal 21–30 ASD = 87 NS = 64	87	86
Verbal 21–30 ASD = 59 NS = 24	81	83

Selecting the correct module for use in the ADOS is also crucial for obtaining an accurate classification. Clinicians and researchers can use the results of standardized tests or parent report to inform module choice, but as an individual’s language often varies in unstructured versus structured environments, the collection of a spontaneous language sample at the beginning of an ADOS administration is highly recommended. Administration of an “easier” module (e.g., selecting module 2 for a child with fluent speech because the tasks are “more fun” when module 3 would be more appropriate) can result in under classification. When in doubt, however, a clinician should adopt a conservative approach and chose a lower module as language difficulties may confound the social demands of a higher one.

Perhaps the most important practice in using the ADOS is to recognize its limitations. The ADOS is only one of multiple sources of information that should be considered when determining whether criteria for ASD are met. It is possible to meet classification thresholds on the ADOS algorithm and *not* meet formal criteria for an autism diagnosis. Conversely, a clinician with information from parent report and observations in different settings may assign a diagnosis of ASD even without an accompanying ADOS classification. The ADOS was developed as a companion instrument to the ADI-R, and indeed, both the ADOS and ADI yield higher sensitivities and specificities together than when used separately (Risi et al. 2006). In the hands of a skilled clinician with ample training and multiple sources of information, the ADOS provides a unique contribution to the observation of social and communicative features of autism and greatly aids in the diagnosis of ASD.

Autism Diagnostic Observation Schedule (ADOS): Toddler Module

Rhiannon J. Luyster
Department of Communication Sciences and Disorders, Emerson College, Boston, MA, USA

Synonyms

ADOS-T

Description

The Autism Diagnostic Observation Schedule – Toddler Module (or ADOS-T; Luyster et al. 2009; Lord et al. 2012) – is a semi-structured assessment of social engagement, communication, and play using a set of planned “presses” within a naturalistic social interaction. It is intended for children under 30 months of age who have a nonverbal mental age of at least 12 months. Other guidelines for use include independent walking and minimal language; once the child masters three-word phrases, the Toddler Module is no longer considered appropriate.

Eleven activities are included in the Toddler Module, along with 41 overall codes. Two algorithms are associated with the module, including one for all children between 12 and 20 months of age and nonverbal children between 21 and

30 months of age and a second algorithm for verbal children between 21 and 30 months of age. These algorithms include formal cutoffs, which are primarily intended for research use and provide a binary classification of ASD or nonspectrum. Each algorithm also has three “ranges of concern,” which are intended for clinical use and provide three classifications of concern: little to no, mild to moderate, and moderate to severe. The Toddler Module can be administered in a professional’s office or playroom, although a familiar caregiver must be present. Codes are completed immediately after Toddler Module completion and are based on all behaviors during the administration. Each code can be scored between 0 and 3, with higher scores indicative of greater abnormality.

Historical Background

The Toddler Module was developed in response to a research and clinical need for a standardized instrument for use in very young children at high risk for, or suspected of having, an autism spectrum disorder (ASD). Research had indicated that the ADOS Module 1 was over-inclusive (meaning it exhibited relatively poor specificity) for children with nonverbal mental ages under 16 months (Gotham et al. 2007). The Toddler Module was developed for use in this very young population and was intended to aid in both clinical and research efforts targeted at children who fell below the floor of the ADOS.

The creation of the Toddler Module was based primarily on the Module 1 of the ADOS (Lord et al. 2000), which provides a series of semi-structured, play-based tasks and activities to probe for a range of behaviors. Module 1 items that were appropriate for infants and toddlers were included, and additional tasks were created based on a review of the literature on early social and communicative development. Some other important changes were made based on current knowledge of early development in children with ASD, including a shift from three classifications on the algorithm (autism, ASD, nonspectrum) to two

(ASD, nonspectrum), based on extensive evidence of the instability of specific diagnoses within the autism spectrum. For similar reasons, an emphasis was placed on using algorithm ranges of concern in order to encourage a focus on clinical monitoring and follow-up rather than assigning a formal diagnosis to a very young child.

Psychometric Data

Instrument development involved both validity and reliability studies (Lord et al. 2012). The validity study was completed using data from 182 children. Analyses were repeated using two overlapping samples, one of which included each child only once and a second that included multiple visits from some children. The final set of 41 codes was selected in order to yield markedly different distributions across diagnostic groups or to have high clinical or theoretical importance. In addition, codes were chosen in a manner that minimized collinearity with other codes or sample characteristics. Two algorithms were generated by selecting items that met theoretical and empirical thresholds for optimal group classification. Each algorithm includes items in two domains – social affect (SA) and restricted, repetitive behaviors (RRB) – and cutoff scores were selected based on maximal sensitivity and specificity. Using formal cutoffs, sensitivity and specificity exceeded 86% on the younger/nonverbal algorithm, and they exceeded 83% on the verbal algorithm.

The reliability study included ratings from 7 independent, “blind” raters on 14 Toddler Module administrations (8 from children with ASD, 3 from typically developing children, and 2 from children with non-ASD developmental disabilities, one child contributed two administrations). Inter-rater reliability was evaluated using weighted kappas for nonunique pairs of raters, with kappas between 0.4 and 0.74 considered good and kappas at or above 0.75 considered excellent. Three codes were not included in the reliability analyses because of limited variability; 30 codes had kappas equal to or above 0.60, and the remaining eight codes exceeded 0.45. Inter-

rater item reliability was measured using percent agreement and the full range of 0–3 scores: the mean percent agreement was 84%. All items exceeded 71%, and 30 of 41 items had exact agreement of at least 80%. Inter-rater agreement on the algorithms’ (younger/nonverbal and verbal) diagnostic cutoffs was 97% and 87%, respectively; inter-rater agreement for ranges of concern was 70% and 87%, respectively. Test-retest reliability was also satisfactory across both algorithms.

Note that although standardized calibrated severity scores are not available as a formal component of the instrument (Lord et al. 2012), research suggests that they may be helpful in reducing the effects of language level on algorithm totals (Esler et al. 2015).

Clinical Uses

Clinical usage of the Toddler Module should be accompanied by other sources of information. The ranges of concern may be useful in providing an indication of the degree to which a child is exhibiting symptoms consistent with an ASD, but in some cases, these behaviors may be attributable to other, non-ASD etiologies. Therefore, informed clinical judgment is critical in interpreting results within a broader developmental framework. Examining the profile of scores across the 41 codes may be useful in identifying areas of difficulty for the child and can help in education and intervention planning.

Autism Family Experience Questionnaire (AFEQ)

Kathy Leadbitter

Social Development Research Group, University of Manchester, Manchester, UK

Synonyms

Autism spectrum disorder (ASD); General health questionnaire-12 (GHQ-12); Pre-school autism communication trial (PACT trial); Pediatric autism communication therapy (PACT therapy); United kingdom (UK); Vineland adaptive behavior scales (VABS); Warwick-edinburgh mental wellbeing scale (WEMWBS)

Description

The Autism Family Experience Questionnaire (AFEQ; Leadbitter et al. 2018) is an ecologically valid questionnaire that measures the intervention priorities of parents/caregivers of children with autism spectrum disorder (ASD) and assesses the impact of interventions on family experience and quality of life. The AFEQ was developed in consultation with parents/caregivers of children with

ASD and was designed to address the paucity of outcome measures that assess parent/caregiver-nominated intervention outcomes for autistic children and their families (McConachie et al. 2015; Morris et al. 2014, 2015). It can be used for both research and clinical purposes.

The AFEQ has 48 items. Items are organized into four domains: (1) experience of being a parent of a child with autism (13 items); (2) family life (9 items); (3) child development (development, understanding, and social relationships; 14 items); and (4) child symptoms (feelings and behavior; 12 items). The questionnaire is designed to be self-rated by parents. Instructions are: “Please read each statement carefully and tick the box which you think best fits your feelings about you, your child with autism and your family life.” Items include both positively and negatively worded statements and are scored on an order scale: 1 = always to 5 = never, with an option for “not applicable”. Items that are negatively worded are reverse scored; individual missing data points can be prorated with the mean score of all items for that participant. The AFEQ produces a total score (range = 48–240) and domain scores which can be used to assess group differences or within-participant/within-group change over time. On the AFEQ a lower score indicates a positive outcome, and a higher score is a poor outcome. There are no clinical or case thresholds.

The AFEQ is being used as an outcome measure in current United Kingdom (UK) and international clinical trials. It is also being used in observational studies in several different countries. We invite other researchers and clinicians to utilize the AFEQ. A copy of the questionnaire can be accessed in open-access at: <https://link.springer.com/article/10.1007/s10803-017-3350-7#SupplementaryMaterial>. Scoring guidelines can be accessed directly from the author (Kathy.Leadbitter@manchester.ac.uk). The questionnaire has been translated from English into several other languages. Please contact the author for further information on available languages and/or the translation procedures. We ask that you appropriately cite our work and keep us informed about your research, its findings, and any planned publications or outputs relating to the AFEQ measure.

Historical Background

The AFEQ was developed prior to and in preparation for the UK Medical Research Council Preschool Autism Communication Trial (PACT Trial) as part of a broader strategy adopted by the trial team and funders to promote the involvement of service users in pretrial research design and out of the recognition that there was a measurement gap in relation to parent-generated outcome measures and assessments of family experience and child and family well-being. The PACT Trial was a two-arm parallel-group randomized controlled trial of Pediatric Autism Communication Therapy (PACT Therapy) – a parent-mediated video-aided communication-focused intervention for preschool children with ASD and their parents. The trial ran between 2006 and 2009 across three UK centers and evaluated the effectiveness of PACT therapy plus treatment-as-usual against treatment-as-usual alone in 152 preschool children with core autism (Green et al. 2010). A subsequent follow-up study assessed outcomes at 6 years after the end of the treatment phase (Pickles et al. 2016). The PACT Trial commissioning and protocol included a pre-specified strategy to develop a new parent-generated change measure of child and family well-being that could be used within the trial and suitable for future intervention research.

The AFEQ questionnaire was developed through three phases. Firstly, a series of pretrial focus groups was conducted with 31 parents of children with ASD to generate a core set of parameters that parents identified as the most important outcomes of a preschool intervention for ASD. Focus group transcripts were analyzed with thematic analysis. A set of 78 individual statements were abstracted from the thematic analysis themes to serve as response items within the draft questionnaire. Secondly, a large pretrial web-based consultation in collaboration with the UK National Autistic Society (www.autism.org.uk) subjected the 78 statements to wider review to evaluate the clarity and usefulness of the items. Using the data from the online consultation, low-performing items were discarded, resulting in a questionnaire with 56 well-performing items. This questionnaire was

rated by 152 parents as part of the baseline and 12-month follow-up assessments of the PACT Trial. Parents reported that they found the questionnaire easy to complete and that they valued the opportunity to report real-life experiences for their children and family on metrics nominated by other parents of autistic children. Following further data cleaning, an additional eight items were excluded as they generated too much missing data. The resulting 48-item questionnaire was named the Autism Family Experience Questionnaire. The 48-item AFEQ was then used in the PACT trial 6-year follow-up study.

A planned analysis within the PACT trial protocol was to use data from the trial to evaluate the psychometric properties of the AFEQ (see below; also Leadbitter et al. 2018). It was also planned to use the questionnaire as a trial outcome measure, to assess the estimation of treatment effect of PACT therapy over treatment-as-usual on parent-prioritized outcomes, family experience, and quality of life. On the 48-item AFEQ total score, there was a statistically significant improvement in the PACT group over the treatment-as-usual group at both trial endpoint (Cohen's $d = -0.29$) and at 6-year follow-up (Cohen's $d = -0.49$). There were also treatment effects at trial endpoint on two domain scores: the “experience of being a parent” domain and the “child development” domain. These findings provided evidence that the AFEQ total score, and to some extent its domain scores, were sensitive to change in response to a parent-mediated intervention for young children with ASD.

Psychometric Data

Descriptive data: In the validation cohort (PACT Trial sample – see above), the range of AFEQ total scores across three measurement timepoints was 64–196, with means of 132–141, medians of 133–141, and standard deviations of 21.3–24.6.

Internal consistency: The AFEQ has good internal consistency. To assess the internal consistency of the AFEQ, we examined the scale reliability based on Cronbach's alpha for the total score and domain scores, calculated from PACT

Trial baseline data. The total score and all domains demonstrated excellent levels of reliability: AFEQ total ($\alpha = 0.92$), parent (0.85), family (0.83), child development (0.81), and child symptoms (0.79).

Criterion validity: We assessed the external criterion validity of the AFEQ against (a) the parental Vineland Adaptive Behavior Scales (VABS; Second Edition; Sparrow et al. 2006), a well-validated parent-rated scale of child adaptive functioning; (b) the General Health Questionnaire-12 (GHQ-12; Goldberg 1992), a well-established measure of adult mental health; and (c) the Warwick-Edinburgh Mental Wellbeing Scale (WEMWBS; Tennant et al. 2007), a widely used measure of adult well-being. The correlations between the VABS total score and AFEQ child development domain score (items 23–36; 14 items) were moderate to strong across the three timepoints ($r = -0.48$ to -0.71 ; positive outcome indicated by a low score on the AFEQ and a high score on the VABS). The correlation between the parent domain score (items 1–13) and GHQ-12 total score was Spearman's $Rho = 0.408$ ($p < 0.001$, $n = 101$; a Spearman's rank correlation was conducted as the GHQ-12 distribution was highly positively skewed). The association between the parent domain score and the WEMWBS total score at trial follow-up was $r = -0.528$ ($p < 0.001$, $n = 103$). The AFEQ therefore showed good convergent validity with well-established measures of child adaptive functioning, parental mental health, and parental well-being.

The psychometric evidence is based on a sample of children with “core autism” aged 2–12 years. It is not yet known how the questionnaire would work outside of these parameters.

Clinical Uses

The AFEQ can be applied in a range of healthcare, child development, educational, or social care settings and developmental settings that support families of children with ASD and similar neurodevelopmental conditions. Its main use would be to make pre- and post-within-participant or within-group comparisons to evaluate the effect of an intervention on parent-nominated intervention

priorities, family experience, and quality of life. At the time of publication, it was in use in this way by several clinicians/clinical teams internationally. The AFEQ could also be used to quantify the experience of families and to make between-family comparisons, in order to identify families who are having a particularly difficult experience and who could benefit from further support.

Autism Family Experience Questionnaire (AFEQ), The

Kenneth Larsen

Oslo University Hospital, Oslo, Norway

Synonyms

Autism Spectrum Disorder (ASD); General Health Questionnaire (GHQ-12); Pre-school Autism Communication Therapy (PACT); Vineland Adaptive Behavior Scales (VABS); Warwick-Edinburgh Mental Wellbeing Scale (WEMWBS)

Description

The Autism Family Experience Questionnaire (AFEQ) is a measure developed to reflect the intervention priorities of parents of children with autism spectrum disorder (ASD), and to assess the impact of interventions on family experience and quality for life (The PACT Consortium et al. 2018).

The AFEQ consists of 48 items in the domains: (1) experience of being a parent of a child with autism; (2) family life, (3) child development (development, understanding, and social relationships); and (4) child symptoms (feelings and behavior) (The PACT Consortium et al. 2018). All items are scored on an order

scale: 1 = always to 5 = never, with an option for “Not Applicable.”

Historical Background

Quality of life has been widely studied; however, the research on quality of life for people with autism is scarce (Burgess and Gutstein 2007). The AFEQ was developed and tested within the large PACT intervention, Trial and Follow-Up (The PACT Consortium et al. 2018). The AFEQ is developed based on focus and online consultations with parents (The PACT Consortium et al. 2018).

In the focus group phase, 31 parents of pre-school or school-aged children with an autism diagnosis were recruited. The participants were recruited from both local clinical services and parent-support groups (The PACT Consortium et al. 2018). The participants attended one of five focus groups, convened and led by members of the PACT Principal Investigator team, and an independent qualitative researcher. The focus groups explored the specific parameters identified as the most important outcomes in a pre-school communication intervention for parents. A qualitative analysis of the focus groups resulted in 78 questionnaire items. Thirty-five parents rated the 78 questionnaire for clarity and usefulness online.

Based on the online rating, revised questionnaire with 56 items were applied with parents within the PACT trial. A further cleaning resulted in the 48-item questionnaire: the Autism Family Experience Questionnaire (AFEQ).

Psychometric Data

To date there is only one study exploring the psychometric data of the AFEQ (The PACT Consortium et al. 2018). The scale reliability of the AFEQ was initially examined based on 140 participants based on Cronbach's alpha for the domain scores and the total AFEQ score. All domains and the total score demonstrated excellent reliability: parent (alpha = 0.85), family

(0.83), child development (0.81), child symptoms (0.79), and total AFEQ (0.92) (The PACT Consortium et al. 2018).

External criterion validity was explored for the child development domain against parental Vineland Adaptive Behavior Scales (VABS). The correlation were significant ($r = -0.478$ to -0.710 , $p < 0.001$) and indicating a moderate to strong association between AFEQ and VABS at three different time-points (The PACT Consortium et al. 2018). The external criterion validity of the parent domain of the AFEQ was assessed against GHQ-12 and WEMWBS at one time-point. The correlation between the parent domain score and GHQ-12 was Spearman's $Rho = 0.408$ ($p < 0.001$) and with the WEMWBS was $r = -0.528$ ($p < 0.001$).

Clinical Uses

The AFEQ are used in the PACT 6-year follow-up study (Sigafoos and Waddington 2016) and may be used as described in the objective – to reflect the intervention priorities of parents of children with autism spectrum disorder (ASD) and to assess the impact of interventions on family experience and quality for life.

Autism in Ecuador

Paulina L. Buffle

Faculty de Psychology and Educational Sciences,
University of Geneva, Geneva, Switzerland

Historical Background

As in other countries from the region, the field of mental health in Ecuador has been documented during pre-Columbian times, the colonial period, and the modern republics. Children and adults with autism spectrum disorder (ASD), especially those situated in the most severe end of the spectrum, may have received treatments available for individuals with atypical and challenging behaviors long before ASD was recognized and named. Different treatments used for mental health conditions have been documented since pre-Columbian times, such as the use of hallucinogens (ayahuasca, bejuco), animals (chickens, guinea pigs), songs, and dances with mythical and religious allusions (Naranjo 1983). In different parts of the country, it is still possible to observe practices of shamanism or crusaderism, offered to individuals with mental health difficulties (Zuniga Carrasco and Riera Recalde 2018), or read billboards advertising the services particularly for children's difficulties, mentioning autism among them. The first hospice and psychiatric asylum, Hospicio Jesus, María y José, was founded under the initiative of the Catholic Church in 1785 in the city of Quito, then a colonial center of the Spanish Crown. Operating on a Western prison model, this center had a

population of individuals suffering from mental health problems but also orphans and beggars (Landazuri 2008).

The birth of psychology in Ecuadorian academic circles is situated toward the end of the nineteenth century. The first chair of psychology was given in 1897 on subjects relating to hypnosis and suggestion by professors of general medicine. The lessons were addressed to teachers trained in philosophy and pedagogy, although the biological paradigm appeared to dominate. The first experimental studies took place shortly after, affirming psychology as a scientific area. The creation of various chairs of psychiatry in different cities succeeded until 1926, influenced by the conference "Psychology and Pedagogy," dictated at the first Ecuadorian Congress of Medicine in 1919 (Zuniga Carrasco and Riera Recalde 2018). By 2007, a total of 17 faculties of psychology had been created in different Ecuadorian universities. One of the most important, the Faculty of Psychological Sciences of the Central University of Ecuador, in Quito, was created in 1972 as a single school, covering four specializations: clinical psychology, special education and psycho-rehabilitation, industrial psychology, and legal psychology.

The first identifications of autism cases likely took place in the 1980s, in the context of psychiatric public and private professional practices, following official recognition of autism by the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III), in 1980 and under the influence of European or North American textbooks that university libraries possessed at that time. From the treatment point of view, psychotherapies and psychopharmacology, such as insulin shock therapy, were used for schizophrenia and related disorders from the 1950s (Aguilar 2013). In the 1960s, nongovernmental institutions were created in order to provide care for individuals with mental health conditions. The first organizations created with this purpose were religious, such as the Order of the Sisters of the Hospital, whose work was based on an agreement with the Ministry of Social Protection and Labor. Other nonprofit and for-profit laic foundations, set up to meet the needs of adults and children with

different types of health problems, appear in the following years. The first private centers intending to provide specific assistance to children with autism, by separating them from children with intellectual disabilities, appeared in the late 1980s (Aguirre et al. 2017 cited in Zuniga Carrasco and Riera Recalde 2018).

Currently, it is not possible to identify any specific programs for autism in the registers of public health agencies in Ecuador. The Ministry of Health published the first *Guide for Clinical Practice: Diagnosis, Treatment, Rehabilitation, and Case Management* in 2017. The Ecuadorian health system is based on public and private practices. The public system comprises two subsystems, hospitals, and state social security system institutions, on the one hand, and institutions dependent on the Ministry of Health, on the other. Two major pediatric hospitals, Hospital Baca Ortiz in Quito and Hospital Dr. Francisco de Icaza Bustamante in Guayaquil, depend on the Ministry of Health and provide general and specialized services. There are also private entities which operate in the public sector, such as the Welfare Board of Guayaquil (Hospital Dr. Robert Gilbert E. Guayaquil), the Child Protection Association of Guayaquil, and the Ecuadorian Red Cross. Public services are funded from the general state budget, extra-budgetary funds, and funds from national and international projects and agreements. Private services are funded by selling health-care services to the public sector; by private health insurers, mainly for the middle- and high-income population (Pan American Health Organization 2017); and by the families themselves. Services for people with autism are offered by pediatricians, neuro-pediatricians, psychiatrists, clinical psychologists, and educators, as well as speech and language therapists and occupational therapists, working in public or private centers and private practices but also in nonprofit foundations which are mainly located in the cities.

As it has been the case in other countries, parents' associations have contributed significantly to obtain recognition of ASD through public conferences and free-of-charge training to parents and teachers. In Quito, a group of parents met in 2012 to ask for official recognition of

autism as a handicap. Parents obtained access to a Disability Card (Carnet de Discapacidad) from the National Parliament, which allows individuals with autism to certain rights. In March 2013, those parents united into an association, APADA, aiming to contribute to the development of awareness programs and to work together with the Ministry of Education and the Ministry of Labor on special education plans. This association has also contributed to the development of the National Agenda for Equality in Disabilities 2017–2021, aiming to support the autonomy and productivity of people with disabilities. This agenda also examines how “to define a national instrument for the diagnosis of the Autism Spectrum” and “to implement the screening and diagnosis of the Autism Spectrum in the national territory” (National Council for Equality in Disabilities 2017, p. 54–55). Together with nine other parent associations, Guayaquil (3), Quito (1), Cuenca (1), Machala (1), Santo Domingo (1), Ibarra (1), Los Ríos (1), and Loja (1), it has formed the “Ecuadorian Federation of Autism Spectrum” (Organizaciones de Autismo buscan 2017). Their objective is to protect the well-being of individuals with ASD and their families, promote public policies, and support the work of other organizations. Other parents’ associations are currently being organized in different cities across the country.

Legal Issues, Mandates for Services

Ecuador is a member of the International Convention on the Rights of the Child (The United Nations 1989), which recognizes and protects access to health and education services, and was the 20th state to ratify the Convention on the Rights of Persons with Disabilities (The United Nations 2006) and its optional protocol that entered into force in 2008. The Ecuadorian State has transposed and clarified those rights in its national legislation. The Law on Disabilities (LOD) of the National Health System (National Assembly of the Republic of Ecuador 2012) guarantees the rights of people with ASD to free access to medicines and equipment, technical and

technological aids, adaptations of study plans, and permanent accompaniment of guides (LOD, art. 33). Other benefits, such as financing construction or remodeling housing and a reduction of 50% in the services of water and electricity, are considered by this law. In the field of education, an agreement intends to guarantee the access of individuals with special needs to special education (Ministerio de Educación 2013). In order to be eligible, individuals with ASD must request the Disability Card. Potential beneficiaries need to justify that they are suffering from a “non-evident and non-visible disability.” They also need to present a report from a medical practitioner or a specialist and the results of additional examinations, which may only be issued by the units of the Complementary and Integral Public Health Net (Ministry of Health n.d.). Autism is defined in this context as a “catastrophic disease,” namely, a pathology or chronic disease which poses a grave risk to the life of the person. Their treatment has a high economic cost and social impact, and, being of a prolonged or permanent nature, they must be part of long-term health plan and generally have little or no insurance coverage (Ministry of Health 2012a). In the particular case of individuals in this situation who are living in critical socioeconomic circumstances, this ministerial agreement contemplates the allocation of a monthly voucher of 240 USD under certain conditions. As described, an important legal framework intending to support the development of individuals with ASD exists in Ecuador. However, some critical gaps in terms of training and access to information on good practices exist, hindering the implementation of rules and policies (Educación Inclusiva en Ecuador hay ley 2019).

Overview of Current Treatments and Centers

Many different treatments are offered in public and private centers, as well as in private practices. They include a considerable variety of methods, such as Floortime, Tomatis, hippotherapy, and others, sometimes not specified. Speech therapies, sensory therapies, and cognitive-behavioral

therapies are also commonly offered. Specific evidence-based treatment services are still scarce. To date, two professionals are registered within the Behavior Analyst Certification Board as BCBAs, one in Quito and one in Guayaquil. Only one professional, in Quito, is currently registered on the official list of certified therapists of the ESDM model. TEACCH strategies and alternative/complementary systems of communication are also used within a variety of settings. Drug treatments, generally intended for comorbidities, are prescribed by pediatricians, neuropsychiatrists, and psychiatrists. The annex number ten of the Guide for *Clinical Practice: Diagnosis, Treatment, Rehabilitation, and Case Management* (Health Minister 2017) provides a list of medication endorsed by this document.

Overview of Research Directions

The document “Priority research areas 2013–2017” from the Ministry of Health defines a certain number of fields that had been chosen according to a list of health problems identified in official registers. Mental health issues are the 11th among 19 categories, in which autism and Asperger’s are considered (Ministry of Health 2012b). However, current research literature indicates that areas related to ASD have been underexplored and studies on prevalence at a national level have not yet been conducted. According to the Guide for Clinical Practice (Ministry of Health 2017), ASD prevalence in a child population of 5 years old or less was estimated to be 0.28% (0.18–0.41%) in 2015. According to data provided by the National Directorate of Disabilities of the Ministry of Health, in 2016, 1,266 people diagnosed with ASD were reported. Of these, 254 cases have been registered with a diagnosis of atypical autism, 792 with a diagnosis of childhood autism, 205 with Asperger syndrome, and 15 with Rett syndrome (as cited in Ministry of Health 2017, p. 11). The reasons why estimates of ASD prevalence in Ecuador are remarkably lower than those reported in Western countries remain unclear. As preliminary evidence, a study aiming to estimate school attendance of children with an

ASD diagnosis in the city of Quito found a proportion of 0.11% among 453 pupils in 161 in regular schools, assessed through interviews with school directors (Dekkers et al. 2015).

Preliminary research on the field of assistive technology has also been conducted in different universities. The research group in Artificial Intelligence and Assistive Technology of Salesian Polytechnic University of Ecuador (<https://www.ups.edu.ec/giata>) has carried out a pilot project aiming to explore the functionality of a mobile tool and a robotic assistant for the diagnosis and intervention of children with ASDs (Galán-Mena et al. 2016, June). A project intending to develop an application to support verbal communication and personal autonomy in children and young people has been carried out at the Universidad de las Fuerzas Armadas ESPE (Cárdenas et al. 2015, October).

A research project aiming to identify potential barriers to diagnosis in pediatric environments has been conducted in cooperation with the School of Pediatrics of the Faculty of Medicine at the Catholic University of Quito, the Faculty of Psychology at the University of Geneva, and the AJ Drexel Autism Institute in Philadelphia, with the endorsement of the Ecuadorian Society of Pediatrics (ESP). The results suggest that, as in many other countries, the pediatric community in Ecuador may be facing obstacles in terms of time for screening, training, and resources adapted to their clinical practices. The results also point to a low number of autism cases identified during the professional life of the participants (Buffle et al. 2019). An additional study, aiming to examine the pediatric community’s perception on screening procedures and tools, suggests a preference for observational procedures, over paper parent-administered questionnaires, as well as a clear interest among professionals in acquiring knowledge and expertise on the identification of early signs (Buffle and Gentaz 2019). A pilot project aiming to study the visual social attention with an eye-tracking is currently being conducted in neurotypical preschool age children in Quito. Eye-tracking measures are increasingly proposed as sensitive biomarkers for ASD, particularly convenient to assess the core social attention deficits

contributing to ASD. Remote eye gaze tracking is a noninvasive technique not requiring participants' overt responses and has not significant technical or ethical limitations (Frazier et al. 2018). Furthermore, measures can be rapidly collected across a wide range of ages and probably in different cultural settings. The present study aims to explore the adaptability of this technique and procedures to an Ecuadorian context (www.unige.ch/fapse/babylab/le-babylab/equipe/projet-en-equateur).

An overview of digital repositories from different universities in Ecuador shows an increasing interest among young bachelors in psychology and pedagogy in fields related to intervention in children with ASD, suggesting a potential for the development of new lines of research. An important research priority is the understanding of the cultural fit and adaptations required to implement evidence-based practices originating from the West (Vivanti 2019).

Overview of Training

Ecuadorian universities currently offer postgraduate studies in pediatrics and neurology. The specialization in neuro-pediatrics is not presently available, and this field relies on professionals trained in other countries who return to work in Ecuador. Currently, a training module for pediatricians and pediatric interns on ASD evidence-based practices is being developed in cooperation with the Department of Pediatrics of the Faculty of Medicine of the Catholic University of Quito (www.unige.ch/fapse/babylab/le-babylab/equipe/projet-en-equateur).

Aiming to facilitate the dissemination of scientific research in the field of ASD, the ESP included a session on "Validated screening tools in Spanish and their importance for a diagnostic process" during the 19th Ecuadorian Pediatric Congress in 2017. The newly created Ecuadorian Society of Neuropediatrics, supporting continuous education on early detection, included a session on "The challenges to diagnostic faced in pediatric settings and validated methods of intervention," during the First Ecuadorian Neuropediatric Congress in 2019. The ESP has also supported in February

2018 the organization of workshops intended for service providers on an evidence-based early intervention model in Quito, in collaboration with trainers certified from the UC Davis MIND Institute.

Education intended to service providers, such as speech therapists, psychologists, and occupational therapists, is primarily offered as a bachelor's degree at many official universities across the country. Training on specific topics has been provided within universities, such as an introductory module on ASD evidence-based practices addressed to students on special education of the Faculty of Education within the Universidad de las Américas in 2018. Several universities in major cities hold ad hoc conferences on ASD from a variety of theoretical backgrounds. Free-of-cost conferences organized by different parents' associations try to raise awareness among the general public and particularly among teachers.

Social Policy and Current Controversies

Current controversies include the terminology used for the diagnostic of ASD. Ecuador's public system mainly relies on the World Health Organization's International Classification of Diseases (ICD-10) (WHO 1993), one of the two official diagnostic systems. As ICD-10, which has conserved the traditional three categories dating back to Rutter's (1978) criteria, coexists with the autism spectrum disorder's description of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) (American Psychiatric Association 2013), confusion about the diagnostic is common among parents and individuals with ASD. Furthermore, some families strongly identify to their child's diagnosis of Asperger syndrome, perceived as less stigmatizing and more descriptive of milder conditions. For this reason, some professionals and parents oppose the disappearing of Asperger's diagnosis (APADA, personal communication, December 2, 2019).

Adapted and validated treatments are another important source of controversy. Media has become an authoritative source for families, and

it is quite common to observe parents requesting advice and recommendations through this channel. Furthermore, a miscellaneous offer of services, particularly for children, with sound, little, or no evidence, is advertised through the Internet. Some parents' associations, mainly based in Spain, provide information on good practices and are becoming well known among family circles in Ecuador (e.g., Autismo Diario). However, information about treatments that have little or no evidence (i.e., "Beware of non-evidence-based treatments," 2019) are still scarce in Spanish. This situation highlights the importance of making knowledge easily accessible for all families, independently of their socioeconomic status or level of education, in order to facilitate informed decisions.

Many other areas of controversy can be identified, such as the profile of professionals qualified to give a diagnosis and to carry out interventions. For the time being, multidisciplinary teams do not seem to be constituted at the public level. In private sectors, a common source of concern for families is related to situations where the professional giving a diagnosis of ASD also carries out an intervention with a method that is familiar to the professional but does not correspond to an individual's need, thus excluding other models or strategies of intervention that could be more suitable. Also, in the field of services, the impact of very short-term trainings open to the public and certifications on methods of evaluation and intervention that have significant variability in terms of duration, theoretical background, evidence, and professional supervision need to be studied. Finally, an important concern for families relates to the lack of visibility given to the needs of adults on the spectrum, especially in the cases when the level of functioning compromises autonomy. Those themes illustrate that an absolute priority must be to provide families an access to knowledge on good practices that enable informed decisions on the assessment, intervention, and support processes at each stage of their children's development. Attitudes toward individuals with ASD are changing as society becomes more aware of needs. Initiatives are no longer taken only by parents' associations but also by civil society, as suggested by the organization of a discussion

forum on the social integration of individuals with ASD, by an Ecuadorian NGO traditionally interested in sustainable development (Territorios Sostenibles, October 2019). The needs and constraints of individuals with ASD may be more visible nowadays. However, awareness among the general population specifically about symptoms' manifestation may still be frail. Indeed, early identification of young children requires families' participation in the decision process that leads to professional assistance. This process may not take place if autistic behaviors do not raise a certain level of concern among parents and professionals or if those behaviors are not understood as signs of a potential developmental disorder. In Ecuador, a study conducted on 183 adults concluded that most participants did not endorse many socio-communicative core symptoms as concerning enough to require professional assistance. Only language impairment and self-injurious behaviors attracted attention as concerning behaviors in young children by more than half of the respondents. On the other hand, most of the participants attributed the causes of autistic behaviors to factors unrelated to ASD or neurodevelopmental difficulties, such as child personality (Buffle et al. 2020). Those results suggest that "red flags" may not be recognized by families and non-trained professionals, which may lead to missing critical developmental opportunities. It also suggests that a substantial number of cases may remain invisible, preventing the estimation of individuals needing services in Ecuador.

Autism in Higher Education: Access, Challenges, and Support Strategies

Ashleigh Hillier¹, Susan W. White^{2,3} and David Schena²

³Psychology Department, Virginia Tech, Blacksburg, VA, USA

Background

The Interagency Autism Coordinating Committee identified the development of services to support transition to adulthood as its first objective within the domain of lifespan research (IACC 2019). Around 50,000 adolescents with autism spectrum disorder (ASD) enter adulthood each year (Shattuck et al. 2012), many of whom have both an interest in higher education and the intellectual

capacity to succeed academically. The developmental period bridging adolescence to adulthood is when multiple essential milestones are generally achieved, including increased independence, autonomy, and responsibility (Arnett 2000). Unfortunately, many youths with ASD either fail to meet typical adult developmental milestones or decline in functioning during late adolescence (Picci and Scherf 2014).

Young adults with ASD often experience lower quality of life than do age- and cognitive ability-matched healthy adults (Bishop-Fitzpatrick et al. 2017). They also face sustained challenges with living independently (Flynn and Healy 2012; Steinhausen et al. 2016) and finding and keeping gainful employment (Engstrom et al. 2003). One pathway to independence in adulthood and financial mobility is through higher education. Based on data from the Bureau of Labor Statistics, education predicts income and people who obtain bachelor's degrees, on average, earn more than those with just a high school diploma (BLS; Torpey 2018). As such, understanding how society, and especially those in mental health and higher education, can best support the needs of college-enrolled and college-bound people with ASD is important.

Transition from High School to College

Federal policies such as the No Child Left Behind Act of 2001 and the Individuals with Disabilities Education Improvement Act have greatly improved educational outcomes for students with ASD in elementary and secondary education (Smith 2005). But while these policy changes have provided more opportunity for students with ASD to pursue a college education, this is not necessarily a smooth or successful transition. Transitioning into college can be both thrilling and difficult for anyone (Shea 2019), but a growing body of research indicates that emerging adults with ASD face unique challenges that can impede access to higher education. Adolescents and emerging adults with ASD often exhibit underdeveloped independence, lagging interpersonal skills, and impaired ability to manage stress

(Elias et al. 2019; Elias and White 2018). Partly because of these factors, it is estimated that only 50% of young adults with ASD pursue a college degree (Taylor and Seltzer 2011), a rate that is lower than the U.S. average college enrollment rate of 70% (U.S. Dept. of Health and Human Services 2017). Prior research also indicates that college students feel more supported academically than socially (Cai and Richdale 2016), a trend which can lead colleges to overlook the social deficits inherent to ASD. However, despite these factors, colleges are still seeing a nationwide increase in applications from students with ASD, and more and more high school students with ASD decide to pursue postsecondary education every year (CITE).

Different College Pathways

Once an adult with ASD decides to go to college, several choices await them. The student must decide on a major, a living arrangement, and indeed the type of college or university they will apply to. These choices are important for all students to consider, especially so for students with ASD. There are multiple different pathways an adolescent with ASD could take, including attending vocational high school, studying at a community college, or pursuing a 4-year degree.

Firstly, where do students with ASD attend? Many students with ASD enroll in community colleges and local institutions. One study reported that around 80% of postsecondary students with ASD were in a community college for at least part of their education (Wei et al. 2014). Some professionals have recommended this pattern as beneficial for students with ASD. For example, according to Adreon and Durocher (2007), Lars Perner (2002) suggested that the increased personal attention found in community colleges can help a student with ASD adjust to the routines and responsibilities of college. Conversely, large universities provide far less opportunity to receive individualized attention, especially in large classes (Freedman 2010). It may also be worth considering what sort of programs colleges have to offer students with disabilities; for example,

Shmulsky et al. (2015) demonstrated that participation in a holistic transition program resulted in students with ASD having a higher first-year completion rate than unsupported typically developing students.

Secondly, what majors do students with ASD choose? Research on this topic is minimal, but studies on the majors chosen by students with ASD suggest that STEM majors are the most commonly chosen areas of study (Baron-Cohen et al. 2007; Fessenden 2013; Wei et al. 2013). In particular, computer science seems to be a popular area of study for these students (Wei et al. 2013). Further research is needed to better understand what students with ASD are interested in studying, so as to better-inform program administrators.

Finally, where do students with ASD choose to live? Some students commute while others live in campus housing. Students with ASD may choose to commute for several reasons. It may be due to family finances and commuting can prevent a family from being charged a housing fee by the college or university (Buescher et al. 2014; Shimabukuro et al. 2008; Wei et al. 2014). It may also be due to personal factors such as deficits in independent living skills (Elias and White 2018; Steinhausen et al. 2016; Van Hees et al. 2015). Conversely, if the student decides to live in campus housing, they may have a roommate. Studies have shown that certain factors in roommates, such as aloofness (preference of solitary activity and decreased social involvement) can play a key role in fostering good relationships with students with ASD, with phenotypes closer to the autism phenotype resulting in higher relationship satisfaction from both roommates (Faso et al. 2016).

Strengths of College Students with ASD

Students with ASD typically bring a variety of strengths with them to college. The prevalence of special abilities and talents among those with ASD has long been recognized (Asperger 1944; Kanner 1943). Around two-thirds of individuals with ASD are thought to possess special isolated skills (Meilleur et al. 2015) which can be

harnessed for success in higher education. Attention to detail, strong memory, adherence to rules and guidelines, passionate interests, and intense knowledge of a particular subject area are commonly noted strengths of these students (Anderson et al. 2017; Gobbo and Shmulsky 2014), as well as openness to feedback and suggestions (Elias et al. 2019). Other strengths which may prove useful in higher education include enhanced perceptual functioning (Motttron et al. 2006), superior pitch discrimination (Heaton et al. 2008), hyperlexia (Ostrolenk et al. 2017), mathematical/calculating skills (Howlin et al. 2009), as well as musical, artistic, and other abilities (Meilleur et al. 2015).

Previous research suggests individuals with ASD tend to do particularly well in STEM areas of study. These students often have a cognitive style that lends itself particularly well to STEM fields: an ability to observe, identify, construct, and apply logical rule-based systems of reasoning to explain the world around them (Cox et al. 2016), i.e., “systemizing” (Baron-Cohen 2009). It has even been suggested that those with ASD may have an innate predisposition for STEM with higher autism rates among children whose parents work in STEM fields (Baron-Cohen 1998; Baron-Cohen and Hammer 1997). Students with ASD may approach problems in science and engineering in unique ways, develop novel and divergent solutions, and show strength, resilience, and determination (Baron-Cohen 2009). Interestingly, students with ASD who pursue STEM fields tend to progress further in their education and are more likely to finish all 4 years or transfer from a community college into a 4-year college or university (Wei et al. 2014). As previously mentioned, college students with ASD are more likely than students in other disability categories, and students in general, to gravitate towards STEM fields, and the efforts of these students are a credit to their fields.

Challenges Experienced by College Students with ASD

Emerging adults with ASD may experience significant difficulties during their college career.

Social interactions, organization and time management, managing anxiety and depression, maintaining motivation, and sensory overload have all been noted as areas of both frequent and severe difficulty for many students with ASD (Alverson et al. 2015; Trembath et al. 2012; White et al. 2016). Loneliness and isolation are common problems for college students with ASD (Madriaga and Goodley 2010). Knowing where to meet other students with similar interests, initiating and maintaining conversations with classmates, and finding ways to connect with other students can all be challenging. Other common situations such as group projects, maintaining appropriate classroom behavior, and in-class debates all demand complex social skills which students with ASD may not have (Cullen 2015). By the students’ own admissions, these social needs often go under-supported (Cai and Richdale 2016).

Furthermore, the college environment is dramatically different from high school, particularly concerning changes in schedule and routine, self-autonomy, and the need for self-advocacy skills (Van Hees et al. 2015). Living on campus also may require negotiating with roommates and independently managing a range of personal responsibilities such as doing laundry, cleaning, self-care, and handling mealtimes. High schools often have a somewhat invisible support system where teachers, staff, and classmates know and understand the student with ASD. Particularly on a large campus, these invisible supports are difficult to replicate in a college environment.

Disclosure of ASD Diagnosis

An additional challenge for students with ASD in college is the issue of disclosure. Many students with a diagnosis of ASD choose not to disclose (Van Hees et al. 2015) for a variety of reasons, which may include relation to self-identity, expected benefits from disclosing, and previous experiences with disclosure. Many college students with disabilities may want to eliminate the label of being disabled to reset their social identity (Marshak et al. 2010). Data from the National

Longitudinal Transition Study-2 indicated that around 33% of students with ASD did identify as “disabled” (Shattuck et al. 2014). The colleges themselves may not do an adequate job of providing information to incoming students about the services and supports which may be available to them and how to navigate the disability services system.

Further complicating the situation, disclosure does not guarantee assistance. One study of disclosing students attending 2-year colleges found that less than half reported receiving any services or accommodations (Roux et al. 2015). Others have reported reluctance to disclose their ASD diagnosis until they encounter a significant problem or are unable to cope (e.g., Gobbo and Shmulsky 2014; Van Hees et al. 2015). Finally, unlike in high school, in college it is the student’s responsibility to take initiative and seek help. Students with ASD, who may have depended upon parents and teachers to set goals (Elias et al. 2019), may fail to access these resources simply because they are not used to doing so.

Attitudes Towards College Students with ASD

Attitudes among students, faculty, staff towards students with ASD are another area of concern. Research has shown a significant lack of knowledge and understanding of ASD among faculty and staff (Glennon 2016; Tipton and Blacher 2014), leading to frustration among faculty and inaccurate interpretations of inappropriate classroom behavior. These and other misconceptions about autism have led to stigmatization and exclusion of these students (Gillespie-Lynch et al. 2015; Gobbo and Shmulsky 2014; Schindler et al. 2015; Wenzel and Brown 2014).

What about students? Student responses vary and seem influenced by major and previous experience. Students often distance themselves from students with ASD (Gardiner and Iarocci 2014) but those more familiar with autism seem to be more accepting (Nevill and White 2011). Students studying engineering and physical sciences have

been shown to be more willing to interact with a student with ASD compared to those majoring in arts and social sciences (Nevill and White 2011). Inclusion in training programs presenting information about ASD has been shown to increase knowledge and decrease stigma among college students (Gillespie-Lynch et al. 2015), since understanding motivation for behavior can help reduce stigma (Butler and Gillis 2011). However, studies by both Gillespie and colleagues and by Matthews et al. (2015) found that training has a greater impact on behavior and cognitive attitudes towards individuals with ASD and less impact on the affect experienced by these trained students.

Related to this work, White et al. (2019) examined student knowledge and attitudes towards other college students with ASD, the underlying factors contributing to such attitudes, and whether attitudes changed over a 5-year period. While the later cohort had greater knowledge and more positive attitudes towards students with ASD, there was no significant relationship between knowledge and attitudes. Even after being presented with an accurate list of traits that might be seen in a student with ASD, students who had previously identified a higher number of aggressive or misleading traits still demonstrated less positive attitudes – their own beliefs still trumped new factual knowledge. These findings imply that despite increasing knowledge and understanding of ASDs in society, negative attitudes remain resistant to change.

Students who personally knew someone with ASD had more positive attitudes toward their peers with ASD, consistent with other research in this area (Gillespie-Lynch et al. 2015; Nevill and White 2011). Students who did not know someone with ASD were more likely to endorse inaccurate traits related to cognitive deficits, perhaps reflective of stereotypes about disability more broadly, which are often perpetuated by a lack of contact. The conclusion that knowledge about ASD does not necessarily mediate attitudes toward peers with ASD is consistent with much of the research on attitudes toward members of minority populations, including those with disabilities and mental health issues (Allport 1954; May 2012; McManus et al. 2011).

Strategies to Support College Students with ASD

With all of this in mind, how can we best support students with ASD? Given the potential for success among college students with ASD, formulating effective support strategies is a priority for an increasing number of higher education institutions. Existing supports available through university counseling centers and learning and academic support services including tutoring and advising are often helpful. Disability services offices also play an important role in setting up academic accommodations which, depending on a student's disabilities and eligibilities, might include extended time for exams, having a note-taker during class, or taking verbal exams (Egan and Giuliano 2009). However, barriers to accessing accommodations are multilayered, beginning with concerns of disclosure, as outlined above. There is a clear need to identify cost-effective programming that can be implemented with efficacy and which improve retention and success for students with ASD (Barnhill 2016).

Supports for Social Skills

As stated previously, college students with ASD often state that they are not receiving adequate social or educational support in this new setting (Cai and Richdale 2016). Students themselves seem willing to attend support groups where they can meet other students with an ASD diagnosis (Van Hees et al. 2015), although colleges offering such groups have reported concerns that students were not receptive to the group, did not show up at the expected time, or that breaking down social skills was not helpful (Barnhill 2016). While an increasing number of institutions are developing tailored support groups, mentoring programs, and special tutoring, empirical support for many of these activities is minimal (Gelbar et al. 2014), and it is not yet clearly understood what supports are most helpful for students with ASD (Cox et al. 2016). It is clear, however, that support for social difficulties is critical (White et al. 2016) and likely has major implications for retention and success.

In part to address these problems, Hillier et al. (2018a) provided a support group program, "Connections," for college students with ASD which had a broad curriculum addressing not only social skills but a range of other potential challenges including academic skills, time and stress management, managing group work, and future plans. Group members indicated significant reductions in loneliness and anxiety and increase in self-esteem at the end of the program. Focus groups were conducted to examine functional changes in academic and social skills, and to hear directly from students themselves, a notable gap in the literature focused on students with ASD (Cox et al. 2016; Gelbar et al. 2014). Five prominent themes were identified in the focus group analysis which reflected how the program had positively impacted participants' skills and coping: executive functioning; goal setting; academics and resources; stress and anxiety; and social. Given that college students typically make their own decisions regarding interventions and services they are willing to receive, the program's social validity was also assessed and participants indicated that the group was acceptable, socially relevant, and useful to them.

Mentoring Programs

Mentoring is a well-established strategy for improving outcomes for a broad range of populations: at-risk youth (Britner et al. 2006), foster children (Rhodes et al. 1999), workplace mentorship (Janssen et al. 2015), and individuals with disabilities (Daughtry et al. 2009). Increasing attention has been paid to the possibility of implementing mentoring programs in higher education institutions for students with ASD. While many factors affect a program's success (Rhodes and DuBois 2008), a meta-analysis of 73 youth mentoring studies identified "best practices" including ongoing training for mentors, recruiting mentors with a background in helping roles or professions, structured activities for mentors and youth, expectations for frequency of contact, mechanisms for support and involvement of parents, and monitoring of overall program implementation (DuBois et al. 2011).

Hillier et al. (2019a) reported on a mentoring program for college students with disabilities, the majority of whom had an ASD diagnosis. The program supported freshmen for one semester and consisted of one-on-one hour-long weekly meetings with a trained mentor, typically an upperclassman at the same school. A structured curriculum with weekly and monthly goals covered topics including socializing on campus, peer pressure, organization and time management, email etiquette, study strategies and academic performance, managing stress, self-care and anxiety, and establishing independence. Mentees were compared with a group of matched students who did not receive mentoring. Self-report measures and focus groups indicated that mentoring had the most impact in knowing how things work at the university, how to meet people on campus, and accessing supports. Although academic outcomes (retention rates, average number of credits earned each semester, and GPA) did not differ between the mentees and a matched comparison group, a follow-up study indicated that mentees continued to experience benefits one-year on. Further, mentors themselves also reported a range of benefits including enhanced interpersonal and communication skills, patience, and compassion, as well as educational benefits and skill development such as thinking on their feet, being supportive rather than condescending, and responding differently to different people based on their needs (Hillier et al. 2018b).

A similar program was implemented in Australia with a group of 10 university students with ASD (Siew et al. 2017). Students met for an hour each week with a trained graduate student and discussed topics based on the needs of the mentees which included time management, academic performance, and communication with professors and peers. Using a pre-post design and a range of self-report measures they found improved social supports and reduced general communication apprehension, although no significant change in anxiety, state communication apprehension, or participants' perceived communication competence. Qualitative analysis of semi-structured interviews indicated that participants appreciated the constant, stable support

from a peer, as well as the individualized nature of the support. Gillespie-Lynch et al. (2017) implemented a two-semester mentoring program for college students with ASD focused on social skills (semester one) and self-advocacy skills (semester two). Participants could access one-on-one mentoring with undergraduate or graduate students, and/or mentor-led group meetings. Again outcomes were positive indicating reduced anxiety and autism symptoms following the social skills training, and increased perceived social support from friends and heightened academic self-efficacy following the self-advocacy training. Mentoring programs focused on preparing for the transition to college prior to matriculation have also shown promise (Burgstahler and Cronheim 2001; Hillier et al. 2019b; Kim-Rupnow and Burgstahler 2004; Lindsay et al. 2016; Patrick and Wessel 2013), as well as summer transition programs specifically for incoming university students with ASD (Hotez et al. 2018; Lei et al. 2018).

Outcomes for College Students with ASD

What happens when students with ASD graduate? The first thing to note is that college is not "job-training," per se. It aims to impart a variety of soft skills, such as problem-solving and critical thinking (Arum and Roksa 2011; Huber and Kuncel 2016; McMillan 1987). This can be a problem for students with ASD, who tend to do better with clear and concrete instructions (Hollander et al. 2011; VanBergeijk et al. 2008), as individuals with ASD often tend to think concretely (Hobson 2012). This can lead to college graduates who are well-taught but who have not been prepared to begin and pursue a career. Job interviews tend to pose a particularly difficult challenge for would-be employees with ASD (Morgan et al. 2014). As nonverbal social behaviors have an impact on interview outcome (Ruben et al. 2015), as well as verbal factors such as prosody, turn-taking, and use of appropriate pauses (Morgan et al. 2014; Nguyen and Gatica-Perez 2015), individuals with ASD often experience difficulty during job interviews.

Despite the challenges, those with ASD who graduate college tend to have better outcomes than those who do not (Migliore et al. 2012; Sung et al. 2015). Participation in postsecondary education is in fact one of the strongest predictors of a good outcome for an adult with ASD (Migliore et al. 2012). Positive outcomes include better job placement, better job retention, and higher wages than their counterparts who do not attend university (Sung et al. 2015). Within college, students with ASD may report high GPAs (Gelbar et al. 2015). Furthermore, as noted by Taylor and Seltzer (2011), college students with ASD sometimes work in addition to studying, meaning that many graduate with not only a degree but with some work experience. Finally, many colleges have career development offices which provide services meant to help students with these “hard skills” needed to earn and keep a job. They teach students how to write a good resumé and offer practice job interviews (Crosby 2009). Some, such as Purdue University’s “Career Closet,” even loan formal interview clothing to students and give fashion advice (“What We Offer,” 2019). These offices and services can prove critical to persons with ASD by teaching the “hard skills” necessary to gain a job (Dey and Cruzvergara 2014).

Future Directions

In summary, an ever-increasing number of individuals with ASD are entering postsecondary education. Researchers and college administrators know enough about these individuals as a group to create services and programs designed to help students with ASD succeed in spite of challenges they may experience. High schools, especially those which tend to send many students to postsecondary education, can also help students with ASD prepare for the transition to college. However, further research is needed to better understand this population. Future work could gather data directly from students with ASD themselves as few studies have asked what they think is effective for preparing to transition and strategies to promote success once matriculated. Although

we have come a long way in recent years, more work is needed to understand the experiences of college students with ASD and the factors that contribute to positive outcomes.

Judgments; Justice; Law; Legal system

Definition

Autistic people are thought to be more likely than non-autistic people to come into contact with the justice system, including the courts. This does not imply that autistic people are more likely to offend; indeed, the limited available evidence suggests that autistic people are generally as law abiding (if not more so) than the general population. Due to vulnerabilities experienced by some autistic people (e.g., diminished social insight coupled with feelings of social alienation and eagerness for peer approval), much of the contact that autistic people have with the justice system may be as victims or witnesses (e.g., because of a limited ability to detect suspicious behavior and mal-intent by others, heightening their risk of manipulation).

Different countries have different judicial systems, but research on autism in the courtroom has

tended to focus on criminal proceedings (addressing matters in relation to criminal law, e.g., murder, robbery, motoring offences) or family proceedings (addressing matters in relation to family law, e.g., custody of children, divorce proceedings). Irrespective of the type of court (e.g., criminal or family), or the capacity in which the autistic person is involved in the justice system (e.g., witness or defendant), there are aspects of the courtroom environment and proceedings that are likely to be particularly problematic for an autistic person.

First, “unusual” behavior or communication in the courtroom may lead to negative perceptions of autistic people (particularly as defendants). This may be particularly relevant if an autism diagnosis is not known or disclosed. Cooper and Allely (2017), for example, refer to the case of *R v Sultan*. Mr. Sultan was a defendant diagnosed as autistic after his trial for rape and indecent assault. Mr. Sultan’s “strange behavior in court, such as reading a book while [the alleged victim] gave her evidence” was noted. Yet even if an autism diagnosis is known pretrial, the autistic witness/defendant may choose not to disclose their diagnosis: research has shown that autistic people are reluctant to tell legal professionals about their diagnosis due to fear of discrimination.

Second, knowledge and experience of autism among courtroom professionals may be pertinent. While many courtroom professionals (e.g., barristers, judges) report that they feel knowledgeable about autism, they often add that they do not feel confident about working with autistic people and are not overly satisfied with their interactions with autistic people in the courtroom. Calls for greater training on supporting autistic people in the courtroom should, therefore, have a distinctly practical focus: improving legal professionals’ self-efficacy, and not just their knowledge of autism.

Recent research has focused on how autistic people are perceived in the courtroom by judges and juries, and this has yielded mixed findings. While concerns have been raised about the perceived unreliability of autistic witnesses, mock jurors’ perceptions of autistic witnesses tend to be positively impacted by the knowledge of a person’s autism diagnosis. This does, however,

appear to depend on the degree of “unusual” behaviors displayed by the witness. Moreover, some evidence suggests that an autism diagnosis may have little impact on decisions of criminal responsibility, while other evidence suggests that judges and jurors may take autism into account as a mitigating factor or that an autistic offender may be less likely to receive a custodial sentence (instead being diverted out of the justice system). Legal professionals report that they struggle to determine what emphasis to place on diagnosis and other information from psychiatric reports; while some use it as a mitigating factor, others consider autism to be an aggravating factor.

Overall, research has shown that autistic people and their families often feel dissatisfied with their experiences in the courtroom. To improve their experiences, an autism diagnosis should, at least, enable reasonable adjustments to ensure fair access to trial, for example, with the provision of an intermediary (a trained professional whose role is to facilitate effective communication between vulnerable witnesses and members of the justice system, a role that is limited to a few countries at present, e.g., England, Australia). It is also vital that appropriate support is provided for both witnesses and defendants (some support, e.g., from an intermediary, is limited to witnesses only). Finally, assistance should also be given to juries, to make decisions informed by expert insights of the needs and complexities associated with autism.

Given the reportedly high rates of autistic people engaged with the courts, this topic is an important avenue for future research, alongside more general awareness and consideration of autism within the courtroom.

Autism Research Priorities

Thomas Frazier
Autism Speaks, New York, NY, USA
Cleveland Clinic Children's,
Cleveland, OH, USA

Definition

Autism research priorities are the areas of scientific study that are deemed most important and valuable by stakeholders within the autism community, including people with autism, their family members and caregivers, and autism service providers (e.g., physicians, educators, etc.). Generally, these priorities range from basic

science studies that include investigations of etiology and neurobiological mechanisms, to translational research focused on using basic knowledge to develop novel interventions and supports, to applied science research testing the efficacy and effectiveness of treatments, and, finally, to clinical implementation studies focused on real-world dissemination and use of effective interventions (Frazier et al. 2018). Research priorities engage the full complement of scientific and clinical disciplines including genetics, molecular and systems biology, neurology and neuroscience, immunology, physiology, psychiatry, behavioral and intervention science, speech and communication science, and public health to advance research and practice for autism (IACC 2012).

Historical Background

Over the last two decades, research has identified and begun to explain the etiologic and phenotypic heterogeneity of autism (de la Torre-Ubieta et al. 2016; Georgiades et al. 2014). Beginning in the early 1990s, the prevalence of children identified with autism spectrum disorders began to increase (Fombonne 2009). This has been attributed to a combination of increased awareness of the disorder's early signs and symptoms among families and health-care providers as well as, in 2013, a change to the clinical definition of autism spectrum disorder. What is now known as autism spectrum disorder was previously classified as three distinct diagnoses in the Diagnostic and Statistical Manual of Mental Disorders (DSM): autism, Asperger's syndrome, and pervasive developmental disorder – not otherwise specified (PDD-NOS). The fifth edition of the DSM (DSM-V) featuring this more expansive definition was published in 2013. Between 2002 and 2014, the prevalence estimates of this heterogeneous group of disorders increased from 1/150 to 1/59 (Baio et al. 2018).

Increasing prevalence rates in the last 20 years have been followed by increased research funding to understand autism's biological underpinnings and develop more effective interventions. Increases in public and private/nonprofit

research funding have been an important part of promoting autism research advances. From 2008 to 2015, autism research funding in the USA (public and private) expanded from \$222 million to \$343 million, with projected increases to \$496 million by 2020 (source: NIH RePORTER) (National Institutes of Health 2017). Expanded funding has paralleled increases in the number of autism publications, from less than 500 in 2000 to more than 3500 in 2015 (source: US National Library of Medicine PubMed database search) (Ncbi Resource Coordinators 2017). Similarly, the number of patent applications relevant to autism increased from 4 in 2001 to almost 60 in 2014 (source: US Patent and Trademark Office AppFT) (US Patent and Trademark Office 2017). While not every research area has received strong funding, investigations have proceeded on a wide front, with prominent topics ranging from genetics and basic neuroscience to cognition and behavior to clinical trials. As the cohorts of young children diagnosed during the expansion of autism awareness have progressed to adolescence and early adulthood, research into understudied topics such as adult transition has also increased. However, absolute funding levels for services and lifespan research – areas important to the quality of life of many individuals and families – lag behind (Interagency Autism Coordinating Committee (IACC) October 2017).

Research priorities in the late twentieth and early twenty-first century focused on understanding if and how autism is inherited, the early emergence of neurodevelopmental symptoms, and understanding the outcomes of existing pharmacologic and behavioral treatments. Over three decades, from 1980 to 2010, these studies identified strong heritability but only a handful of rare genetic causes (Huguet et al. 2016), earlier emergence and ability to identify autism symptoms (Pierce et al. 2019), variable but generally weak pharmacologic benefit outside of atypical antipsychotics for challenging behavior (Goel et al. 2018), and positive short- and long-term outcomes from behavioral treatments (Tiede and Walton 2019; Schreibman et al. 2015; Gengoux et al. 2019; Green et al. 2017; Rogers et al. 2019). The early emergence of autism symptoms and the existence of effective early intervention have

driven the current emphasis on early screening, diagnosis, and intervention. In turn, this emphasis has improved cognitive, functional, and symptom outcomes as well as overall quality of life for many people with autism and their families. However, even through 2019, much work remains in understanding the etiology of autism and translating these findings into more effective biological interventions.

Traditionally, genetic and other basic science investigations of autism spectrum disorder have failed to include the perspectives of stakeholders in the development of research aims. This oversight has often extended to clinical trials and other applied scientific studies. Including viewpoints of those with autism and their families as well as those who work directly with persons on the spectrum, such as therapists and teachers, in decision-making can increase the benefits that future research delivers to individuals and families, iteratively improving community engagement and participation in research (Fletcher-Watson et al. 2017b). The viewpoints of scientists conducting research are important as well, as ideally there is some alignment between researchers and stakeholders directly affected by autism. If there is misalignment, it would be crucial to consider barriers that might discourage scientists from devoting their research to areas considered high priority from those affected directly by autism, such as available funding directed toward those areas.

The preferences and perspectives of stakeholders, including those with autism, their families, and service providers, will differ depending on each person's specific challenges. Understanding the wide range of needs and desires of people that are directly affected by autism, including persons on the spectrum and families, as well as providers (clinicians and educators) and researchers, is important in setting priorities regarding autism research funding (Pellicano et al. 2014a, b). Over the past few years, several investigations have been conducted to better understand research priorities of autism stakeholders and how these priorities can inform future research foci, design, and conduct as well as funding priorities for major funding organizations.

Current Knowledge

In its most recent analysis of autism funding in the USA, the Interagency Autism Coordinating Committee (IACC) reviewed all autism-related projects, which totaled more than \$406 billion dollars in 2010. While previous analysis has found the majority of funding for autism research goes to basic science, including risk factors, biological mechanisms, and genetic factors, the distribution of funding shifted significantly between 2000 and 2010. US funding analyzed by IACC found even priority research areas – biology, risk factors, treatments/interventions, services, infrastructure and monitoring, diagnosis, and lifespan issues. Of these, six received between 11% and 22% of the total autism research funding in 2010. Lifespan issues, however, remained the least-funded research priority area at 2% of total funding (IACC 2012). In several studies, stakeholders ranked lifespan issues and adult outcomes as top research priorities (Gotham et al. 2015), in contrast to its comparably lower current funding levels compared with other research areas.

Community and systemic factors contribute significantly to outcomes of youth with autism transitioning to adulthood – one of the primary targets of lifespan issues in autism. Reviews of the literature and additional studies have identified gaps in the current knowledge regarding these factors. These include the social-ecological determinants of transition outcomes, the broad range of support needs for adults with autism, lack of longitudinal data, lack of comparison of research findings from studies with small sample sizes or other limitations, and outdated quality of life indicators (Shattuck et al. 2018). Stakeholders continue to identify as a top priority the need for more information on building community capacity to support successful outcomes and how to improve systems of care across educational, health, employment, and community settings (Shattuck et al. 2018).

Overall, the pattern of results highlights the importance of collaborating with people with autism and their family members in developing scientific research priorities and the funding process (Pellicano et al. 2014a). Researchers should also consider the broad range of stakeholders'

perspectives when developing their research aims and designing studies. Including multiple caregivers, clinicians, educators, and (of course) people with autism may be important to the development and design of studies to ensure adequate coverage of the large variability of perspectives. Meaningful input from people with autism and their families has the potential to increase the ability to translate findings into practice and make sure outcomes can impart real benefits.

Recognition of the importance of inclusion is driving a movement toward a participatory model to meaningfully engage people with autism and their caregivers and advocates in all aspects of research (Fletcher-Watson et al. 2019). Features of participatory research include collaboration and open dialogue with autism community representatives; listening to and including their feedback in research priorities, funding, aims, and design; and acknowledging a lack of power equity between researchers and study participants in most settings.

People with autism tend to rate researcher priorities as a bit less important than other stakeholders. This may reflect a desire by many verbal, cognitively able people with autism to express that their condition should be understood and accepted rather than pathologized. Some studies have found that current autism research funding levels are not consistent with the priorities of the autism community (Fletcher-Watson et al. 2019), although funding trends show movement in that direction. Some studies in Europe have shown that adults with autism have less favorable attitudes about research than the general population and dislike the clinical terminology “at-risk” when used to describe infants in research studies (Gillespie-Lynch et al. 2017; Fletcher-Watson et al. 2017a).

Applied research tends to be rated as having higher importance than basic or translational science areas, particularly by people with autism. This may reflect the strong desire to identify and implement more effective interventions and supports in the near future. For people with autism, lower ratings for basic science may also reflect a lower average desire to identify etiology versus focusing on acceptance, understanding and modifying current policies and systems to be more supportive and inclusive.

Adult transition, lifespan issues, health and well-being, and co-occurring medical and mental health conditions appear to be very important topics across most stakeholders. Among autism stakeholders who responded to a 2018 survey, areas of applied science are generally deemed more important and valuable than basic science to community stakeholders (Frazier et al. 2018). This reflects the needs and wants of people in this community for quicker access to better treatments and solutions to common challenges. Applied science areas include screening and identification; co-occurring conditions; medical interventions, devices, and other technology; adult transition; lifespan issues; and health and well-being. Respondents gave their highest ratings to research focused on co-occurring conditions, health and well-being, adult transition, and lifespan issues. These results can guide decision-making by public and private funders when developing science funding priorities and engaging in science dissemination activities.

However, basic biological science was also rated an important and valuable area of scientific research by these stakeholders. Basic biological science areas include genetics; molecular studies; cellular studies; animal models; environmental risk and protective factors; biomarkers; immunity and inflammation; and metabolic and mitochondrial function. These topics remain important research priorities due to their potential to lead to better understanding and future treatment options.

Autism research priorities considered primary targets by IACC in the USA include (IACC 2012):

Diagnosis: Diagnostics research aims to develop and validate tools to accurately diagnose autism, look for early signs and biomarkers of risk for autism, define the subtypes or subgroups of people with autism who share similar symptoms and features, and define concretely symptoms that can be reliably and effectively used in autism evaluation.

Biology: This priority area explores the biological mechanisms that underlie the core features of autism and identifies potential targets for interventions to improve function, skill development, and quality of life. Historically, this

research area has focused on early development from the prenatal period through infancy and elementary school age as a means for lowering the potential age for diagnosis and promoting the earliest possible interventions where needed. It also includes investigating the genetic basis for these biological factors.

Risk Factors: Looking for risk factors for autism includes identifying genetic risk factors and genes that cause autism. More recently, this area has broadened to include studying the microbiome and other environmental influences on gene expression (epigenetics).

Treatments/Interventions: This priority area explores the safety and effectiveness of interventions for impairment of function related to core autism features like communication and behavior, as well as other dimensions such as quality of life, mental health, various therapies (e.g., speech, occupational, ABA), and medications. Research in this area also looks for information about medical conditions that often accompany autism and ways to appropriately care for these conditions.

Services: Research into autism services includes various areas, including access to services, dissemination of evidence-based practices, and training of providers.

Lifespan Issues: This research area targets interventions, services, and supports across the lifespan into adulthood, their impact on adult health and quality of life, and the process of transition to adulthood and systemic influences on successful transition.

Infrastructure and Surveillance: Research infrastructure establishes systemic mechanisms to track changes in population outcomes over time. It includes developing networks of researchers to share data, establishing data repositories and biological repositories, and implementing research technology, tools, and protocols to create and access standardized data.

Future Directions

Adult transition, in particular, is garnering increasing attention, both within the broader

autism community and by funding agencies (Gotham et al. 2015). In the early to mid-2000s, increasing diagnosis of autism among childhood cohorts led to an emphasis on early identification and intervention. As these cohorts move through adolescence and into adulthood, the community recognizes the need for evidence-based practices and processes that facilitate a successful transition to adulthood.

While research on adult transition – particularly descriptions of the challenges – has increased, at present there are few evidence-based practices to address this massive public health need. Similarly, little data exist on the lifespan development of autism and issues that might accompany aging. It is likely that both public and private funding will be needed to adequately fill these gaps, raise our understanding of the successes and challenges faced by adults with autism, and develop evidence-based practices that can facilitate health and well-being throughout the lifespan. Autism Speaks, for example, will award nearly \$2.6 million in 2019 on four multi-year studies on issues around transition to adulthood for people with autism.

Federal agencies are also addressing the dearth of knowledge about the range of health and support services facing the adult autism population. The US Congress passed the Autism CARES Act of 2019 as a renewal of previous federal legislation that outlines federal research, service coordination, and surveillance of autism in the USA. The original legislation established the infrastructure need for the Centers for Disease Control and Prevention to study and monitor autism across the country. This infrastructure supports five networks and eight autism intervention research projects (Association of University Centers on Disabilities 2019) to identify areas of need, including screening and intervention services, shortages of qualified personnel in autism diagnosis and treatment, and identifying evidence-based practices for autism and related conditions. The legislation also established the Interagency Autism Coordinating Committee (IACC) to coordinate autism activities among federal agencies and public organizations and advise the Health and Human Services Secretary

on autism science and policy. IACC has identified seven research priority areas in its strategic plan: biology, risk factors, treatments and interventions, services, lifespan issues, infrastructure and surveillance, and screening and diagnosis.

As autism services and research funding has grown, so has our understanding of the health disparities facing many people with autism in certain communities (Karpur et al. 2019). Research into these disparities spans health-care access and utilization, health-care quality, and service quality and delivery and identifies determinants of health. Research is ongoing into the cultural, economic, social, racial, ethnic, policy, and other systemic barriers to autism care in underserved populations, as well as into mechanisms to resolve these disparities. These efforts include the development of valid, reliable, and culturally appropriate diagnostic tools, measures, and interventions for underserved and low-resource populations internationally (Daniels 2019).

Autism Science Foundation

Alison Singer

Autism Science Foundation, New York, NY, USA

Major Areas or Mission Statement

The Autism Science Foundation is a 501(c)3 non-profit that supports autism research by providing funding directly to scientists conducting cutting-edge autism research. ASF also shares information about autism with the general public and serves to increase awareness of autism spectrum disorders and the needs of individuals and families affected by autism. The organization was founded in 2009 by Alison Singer and Karen London, parents of children with autism.

ASF adheres to rigorous scientific standards and values and believes that outstanding research is the greatest gift that can be offered to families.

The Autism Science Foundation's mission is premised on the following facts and principles:

- Autism is known to have a strong genetic component. Research must aim to discover the mechanisms of action that trigger autism, as

well as safe, effective, and novel treatments to enhance the quality of life for children and adults currently affected.

- Early diagnosis and early intervention are critical to helping people with autism reach their potential, but educational, vocational, and support services must be applied across the lifespan. Science has a critical role to play in creating evidence-based, effective lifespan interventions.
- Vaccines save lives; they do not cause autism. Numerous studies have failed to show a causal link between vaccines and autism. Vaccine safety research should continue to be conducted by the public health system in order to ensure vaccine safety and maintain confidence in our national vaccine program, but further investment of limited autism research dollars is not warranted at this time.

Major Activities

ASF provides pre- and postdoctoral research fellowships to support promising young researchers working to discover the causes of autism and develop new treatments. The foundation also offers grant to highly dedicated undergraduates to support summer research and to medical school students to support gap-year research.

ASF hosts the annual autism “TED” talks in New York City and San Francisco each year. These days of learning are designed to bring autism researchers and community stakeholders together to exchange ideas. The foundation also supports an annual symposium to share new school-based autism treatment research with classroom teachers.

ASF produces an award-winning weekly “Autism Research” podcast and disseminates research information to families via multiple social media platforms.

In 2017, ASF launched the Autism Sisters Project in an effort to understand why four times as many boys as girls are diagnosed with autism and to study autism’s female protective effect.

ASF also sponsors the international Autism Baby Siblings Research Consortium, which studies the earliest signs of autism, and recently

launched the Next Gen Sibs project to measure recurrence risk and learn about early signs in the children of unaffected siblings.

ASF serves as the community outreach partner for the international Autism BrainNet, encouraging families all over the world to donate postmortem brain tissue for research.

ASF works closely with other health-care entities, including the American Academy of Pediatrics (AAP), the Centers for Disease Control and Prevention (CDC), and the National Institutes of Health (NIH), to ensure that accurate information about autism spectrum disorders is widely available. ASF’s leaders and board members are frequently called upon by major news media to comment on issues relevant to autism research and public policy.

ASF also has major projects underway to study best practices for supported employment, to encourage more families to participate in autism research, to prevent wandering by children with autism, and to encourage families to vaccinate their children and pursue evidence-based treatments.

ASF’s president, Alison Singer served for 12 years as a public member of the Interagency Autism Coordinating Committee. The Interagency Autism Coordinating Committee (IACC) is a federal advisory committee that coordinates all efforts within the Department of Health and Human Services (HHS) concerning autism spectrum disorder (ASD). Through its inclusion of both federal and public members, the IACC helps to ensure that a wide range of ideas and perspectives are represented and discussed in a public forum. This committee provides advice to the Secretary of Health and Human Services regarding federal activities related to autism spectrum disorders, drafts an annual strategic plan to guide federal spending on autism research, and reports annually on the most promising autism research findings.^t

ASIEP-2

Description

The Autism Screening Instrument for Educational Planning (ASIEP; Krug et al. 1978) was created to facilitate autism diagnoses and to monitor the educational progress of individuals with autism (Arick et al. 2005). First created in 1978, the ASIEP was revised in 1980 and a second edition, the ASIEP-2, was released in 1993 (Krug et al. 1980, 1993). The authors claim that the ASIEP-2 can identify individuals with high levels of behaviors associated with autism (Frye and Walker 1998) and can be applied to individuals with autism from age 18 months to adults (Olm and Oswald 1998). The autism behavior checklist (ABC) is the most widely used subset of the ASIEP (Olm and Oswald).

Historical Background

The ASIEP was first created in 1978, with the ASIEP-2 following in 1993 (Krug et al. 1978, 1993). The ASIEP was designed to provide clinicians with an additional measure to diagnose

autism (Arick et al. 2005). The ASIEP-2 is different from other diagnostic measures, except the PDD behavior inventory (Cohen and Sudhalter 2005), in that it also provides information helpful in monitoring progress and in creating educational programs tailored to the specific needs of the individual with autism.

Psychometric Data

The ASIEP-2 is comprised of five separately standardized subtests: autism behavior checklist (ABC), sample of vocal behavior, interaction assessment, educational assessment, and prognosis of learning rate (Krug et al. 1993). For each of the subtests, raw scores can be converted to standard scores using tables provided in the ASIEP-2 manual (Olm and Oswald 1998). The ABC can be used for individuals of all ages and levels of autism, while the other four subtests are to be used with individuals whose language and social functioning are between 3 and 49 months (Krug et al.). The ASIEP-2 is meant to be used by professional educators and requires that the examiners are knowledgeable about autism and have had at least three weeks of interaction with the child being assessed (Frye and Walker 1998). Overall, the ASIEP-2 has been shown to have adequate validity and reliability (Frye and Walker). The diagnostic validity has been questioned by other researchers who have found the measure to be an adequate screening measure to identify individuals with high levels of behaviors associated with autism, but not a sufficient diagnostic tool (Volkmar et al. 1988).

The autism behavior checklist (ABC) is a 57-item checklist of behavioral characteristics and is meant to be filled out by individuals being assessed, their parents, and their teachers. Items fall into five behavior categories: sensory, relating, body and object use, language, and social and self-help. Each item is weighted from 1 to 4, and the sum of the scores from the five categories is calculated to produce the total score (Olm and Oswald 1998). Krug et al. (1980) reported good interrater reliability. However, due to some concerns about reliability and validity resulting from their evaluation of the ABC, Volkmar et al. suggest that the ABC is best used as a screening measure for

individuals with frequent autistic behavior, rather than as a diagnostic tool (Volkmar et al. 1988).

The sample of vocal behavior (SVB) subtest assesses the characteristics of preverbal and emerging spontaneous language in the areas of repetitiveness, noncommunication, intelligibility, and babbling (Olmi and Oswald 1998). The goal is to elicit 50 vocalizations from the child to score. Scoring categories include variety, function, articulation, and length. Psychometric studies of the SVB have demonstrated acceptable reliability and validity, but had small sample sizes and thus were less rigorous than those applied to the ABC (Olmi and Oswald). Overall, the authors found that the ASIEP-2 had high test-retest reliability (Frye and Walker 1998). In addition, significant differences between the utterances of preschool- and school-age children with autism compared to those with typical development were observed in standardization studies of matched samples.

During the interaction assessment subtest, four types of behaviors are assessed: interaction, constructive independent play, no response, and aggressive negative. Rater reliability is dependent on training and experience (Olmi and Oswald 1998). One study using the interaction assessment found high median agreement (89%) among the ratings (Frye and Walker 1998). Other reliability statistics are unavailable for this measure.

The educational assessment subtest is designed to assess the child's abilities in five areas: staying in seat, receptive language, expressive language, body concept, and speech imitation (Olmi and Oswald 1998). The educational assessment is intended to assess skills that most children with autism lack (Frye and Walker 1998).

The prognosis of learning rate subtest was created to assess the individual's ability to learn newly presented information based on reinforcement procedures and without verbal or physical cues (Olmi and Oswald 1998). There is limited psychometric data for this subtest.

Clinical Uses

The ASIEP-2 was created not only as an assistive diagnostic tool but also as a method to track

individual progress and aid in the creation of appropriate education strategies (Krug et al. 1993). One way that the ASIEP-2 differs from other psychological diagnostic measures is that it is designed to be administered as often as needed to assess progress without concerns about test-retest effects, as the measure demonstrated a lack of practice effects (Frye and Walker 1998). This makes the ASIEP-2 particularly useful for educational planning. In addition, the ABC can be used in clinical settings to create a behavior description; however, it is not sufficient as a primary diagnostic tool (Frye and Walker).

Autism Screening Questionnaire (ASQ)

► [Social Communication Questionnaire](#)

Autism Services Center (ASC), Huntington, West Virginia

Arlette Cassidy

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Major Areas or Mission Statement

ASC was founded in 1979 on the belief that each person with a developmental disability has the capacity for growth and development. Each individual has a right to services that enhance well-being, quality of life, and opportunities to learn. Each should have access to the most normal and least restrictive social and physical environments consistent with his or her needs. Those with even the most challenging behaviors can respond to dignified interaction in a structured, meaningful program with appropriately trained and supervised staff and the appropriate client/staff ratio. ASC encourages the use of best clinical practices and believes everyone has the right to effective treatment.

Landmark Contributions

Major Activities

Serving people with autism, other developmental disabilities, and those who care for and about them.

Autism Services Center employs trained staff to provide a comprehensive array of services for individuals with developmental disabilities.

Service Coordination: Service coordination services are provided for individuals with developmental disabilities who reside in Cabell, Wayne, Mason, and Lincoln Counties in WV. Service coordination establishes a potentially lifelong process

for accessing a range of services, instructions, and assistance. The service coordinator assists an individual with a developmental disability in making meaningful choices and works to ensure quality, accessibility, accountability, and continuity of support services.

Residential Habilitation: Residential Habilitation services, which occur in a client's residence and in the community, provide instruction and assistance for the acquisition and maintenance of skills, which allow for a client to live and socialize more independently. Residential habilitation services may also include behavioral intervention to reduce and eliminate challenging behaviors and replace them with socially valuable, adaptive behaviors, and skills. Autism Services Center owns and/or supervises residences in the Huntington, WV, area.

Day Habilitation: Day habilitation services take place away from an individual's home and include activities in community environments to facilitate skills acquisition. The programs are designed to assist an individual in achieving increased independence and/or to maintain their current skills in activities of daily living.

Prevocational Training: Prevocational training programs are designed to assist an individual in the acquisition and maintenance of basic work and work-related skills.

Supported Employment: Supported employment services enable individuals to engage in paid, competitive employment in integrated community settings. The services are for individuals who have barriers to obtaining employment due to the nature and complexity of their disabilities. These services are designed to assist individuals for whom competitive employment at or above minimum wage is unlikely without the supports.

Respite Care: Respite care is a service provided to an individual by trained staff due to the short-term absence of the primary caregiver.

Adult Companion Services: Adult companion services are complementary to residential habilitation services and provide nonmedical care, supervision, socialization, and assistance in tasks such as meal preparation, laundry, and shopping.

Therapeutic Consultants: Therapeutic consultants provide training for primary care providers

such as direct care staff and family members in person-specific aspects and methods of positive behavior support intervention and instruction.

Nursing Services: Nursing services are provided by registered nurses (RNs) and licensed practical nurses (LPNs) within the scope of the West Virginia Nurse Practice Act.

Family Support: The family support program allocates funds for services and equipment that are not funded by Medicaid or insurance companies. These funds are to assist individuals and their family with such things as clothing, medical care, wheelchair ramps, and respite based on the needs of the family.

Applied Behavioral Analysis (ABA): The applied behavioral analysis (ABA) program or applied behavior analysis is a scientific approach to understanding behavior, how it is affected by the environment and how learning takes place. It is a mixture of psychological and educational techniques tailored to meet the needs of each individual. ABA methods are used to measure behavior, teach functional skills, and evaluate progress.

Autism Society

Cathy Pratt
Indiana Resource Center for Autism, Indiana
University, Bloomington, IN, USA

Major Areas or Mission Statement

The Autism Society

The Autism Society was founded in 1965 by Dr. Bernard Rimland, Dr. Ruth Sullivan, and a group of parents of children with autism. At that time, little was known about this rare disability. As they met in their living rooms, these parents were determined to create awareness and

understanding of this disorder and to provide support for families living with autism.

The Autism Society mission is to improve the lives of all affected by autism. The Autism Society works to ensure that every child and adult with autism lives an independent, fulfilled, and productive life.

Major Activities

The Autism Society supports individuals with autism and their families through the three critical stages of autism:

- **Early Detection and Intervention:** The Autism Society promotes early identification and access to effective treatment before age 3.
- **Building a Strong Foundation from Childhood through Adolescence:** The Autism Society helps parents and caregivers build education and treatment programs so that each child reaches their fullest potential.
- **A Life of Happiness and Dignity:** The Autism Society works to ensure that every adult with autism has access to services and support systems to ensure they achieve the highest quality of life and personal happiness.

Through its strong chapter network, the Autism Society has spearheaded numerous pieces of state and local legislation and offers family and individual support in over 150 locations nationwide. The Autism Society's website is one of the most visited websites on autism in the world, and its quarterly journal, *Autism Advocate*, has a broad national readership. The Autism Society also hosts a comprehensive national conference on autism that covers issues ranging from early identification to adult options each year. Autism Source, the national information and referral center, and the Autism Society's strong chapter network serve thousands of families each year who are searching for help in their journey with autism.

The Autism Society's national office is headquartered in Bethesda, Maryland, and is governed by a board of directors that includes people on the spectrum. The Autism Society's

Panel of Professional Advisors sets the standards for their Options Policy that governs the organization's programs. The Autism Society's Advisory Panel of People on the Spectrum of Autism is a first-of-its-kind advisory panel comprised solely of individuals with autism, who help Autism Society staff create programs and services that will advocate for the rights of all people with autism to live fulfilling, interdependent lives. The membership base of the Autism Society encompasses a broad and diverse group of parents, family members, special education teachers, administrators, medical doctors, therapists, adult agency personnel, nurses, and aides, as well as countless other personnel involved in the education, care, treatment, and support of individuals on the autism spectrum across the age span.

Recognizing and respecting the diverse range of opinions, needs, and desires of this group, the Autism Society embraces an overall philosophy that chooses to empower individuals with autism and their parents or caregivers to make choices best suited to the needs of the person with autism, a policy it calls the Options Policy. All activities of the Autism Society are guided by the Options Policy. Revisited on a regular basis by the organization, the Options Policy has stood the test of time. It states that:

The Autism Society promotes the active and informed involvement of family members and the individual with autism in the planning of individualized, appropriate services and supports. The Board of the Autism Society believes that each person with autism is a unique individual. Each family and individual with autism should have the right to learn about and then select the options that they feel are most appropriate for the individual with autism. To the maximum extent possible, we believe that the decisions should be made by the individual with autism in collaboration with family, guardians, and caregivers.

Services should enhance and strengthen natural family and community supports for the individual with autism and the family whenever possible. The service option designed for an individual with autism should result in improved quality of life. Abusive treatment of any kind is not an option.

We firmly believe that no single type of program or service will fill the needs of every individual with autism and that each person should have access to support services. Selection of a program, service, or method of treatment should be on the basis of a full assessment of each person's abilities, needs, and interests. We believe that services should be outcome based to insure that they meet the individualized needs of a person with autism.

With appropriate education, vocational training and community living options and support systems, individuals with autism can lead dignified, productive lives in their communities and strive to reach their fullest potential.

In addition to the Options Policy, the Autism Society has created guiding principles to further define their work. These guiding principles include:

- The Autism Society's efforts are focused on meaningful participation and self-determination in all aspects of life for individuals on the autism spectrum and their families.
- The Autism Society promotes individual, parental, and guardian choice to assure that people on the autism spectrum are treated with dignity and respect.
- The Autism Society proactively informs, influences, guides, and develops public policy at the federal, state, and local levels, including setting agendas for policymakers and legislators, for the benefit of the autism community.
- The Autism Society is the respected voice of the autism community and the primary source for information by providing timely, frequent, relevant, and professional communication.
- The Autism Society works to ensure that every chapter is a successful chapter, sustained by a collaborative relationship between the national office and chapters to realize mutual benefit and to protect the interests of both.
- The Autism Society advocates for multidisciplinary approaches to autism research focused on improving the quality of life for individuals across the autism spectrum and their families.

- The Autism Society works to ensure financial self-sufficiency and growth for all Autism Society operating units and integrated operations across all levels of the Autism Society.

At the very core of the Options Policy is the belief that no single program or treatment will benefit all individuals with autism and that ultimate parents should have informed choices. Furthermore, the recommendation of what is “best” or “most effective” for a person with autism should be determined by those people directly involved – the individual with autism, to the extent possible, and the parents or family members.

Autism Speaks

Geraldine Dawson¹ and Michael Rosanoff²

¹Department of Psychiatry, University of North Carolina, Chapel Hill, NC, USA

²Autism Speaks, New York, NY, USA

Major Areas or Mission Statement

Autism Speaks is North America’s largest autism science and advocacy organization. Its goal is to change the future for all who struggle with autism spectrum disorders (ASD). Autism Speaks is dedicated to funding global biomedical research into the causes, prevention, treatments, and cures for ASD; raising public awareness about ASD and its effects on individuals, families, and society; and bringing hope to all who deal with the hardships of this disorder. The organization is committed to raising the funds necessary to support these goals. Autism Speaks aims to bring the autism community together as one strong voice to urge the

government and private sector to listen to the concerns and take action to address this urgent global public health crisis. The core values reflected in Autism Speaks’ mission statement are (1) recognition that individuals with ASD and their families often face struggle, which inspires a sense of urgency; (2) commitment to discovery through scientific excellence; and (3) the belief and commitment that parents are partners in this effort.

Landmark Contributions

Funding Autism Science

Since its inception in 2005, Autism Speaks has made enormous strides, committing over \$170 million to research through 2014. In support of its mission to improve the future for all who struggle with ASD, Autism Speaks provides funding along the entire research continuum – from discovery to development to dissemination – for innovative projects that hold considerable promise in significantly improving the lives of persons with autism. Annually, Autism Speaks accepts applications through a number of grant funding mechanisms for investigator-initiated research projects. This includes cornerstone mechanisms such as the Pilot, Basic & Clinical, Treatment, and Predoctoral Fellowship Awards, as well as targeted mechanisms including Post-doctoral Fellowships in Translational Autism Research and the Suzanne and Bob Wright Trailblazer Award.

Assessing the Impact of Research Grant Funding

A survey was conducted to assess the outcomes and impact of Autism Speaks-funded grants completed by 2010. The vast majority (82%) of respondents reported the major finding as a novel discovery, while only 5% reported a negative result. The impacts of these research findings were most often to inform future research strategies and translate basic science discoveries into novel diagnostic and treatment methods. The 107 completed research grants resulted in over 1000 presentations at scientific conferences,

scientific abstracts, and peer-reviewed journal publications. For fellowship grants that aim to attract new scientists to the field of autism, 88% of fellows reported that it was their first experience in autism research and 95% intended to stay in the field. Finally, for each dollar Autism Speaks invested in these grants, investigators secured \$10 in additional funding, with close \$100 million dollars in leveraged funding to date including over \$77 million in federal grants.

Dissemination of new knowledge and building upon existing findings are critical to maximizing the impact of Autism Speaks' research investments and to accelerating the pace of scientific discovery. To ensure that new knowledge resulting from Autism Speaks-supported research can be accessed, read, applied, and built upon, the organization expects its researchers to publish their findings in peer-reviewed journals. It is a condition of Autism Speaks' Public Access Policy that all peer-reviewed articles supported in whole or in part by its grants must be made available in the PubMed Central online archive.

Science Programs and Initiatives

In addition to investigator-initiated research grants, Autism Speaks supports a number of targeted clinical programs and initiatives. The Autism Treatment Network (ATN) is the first network devoted to addressing the medical conditions associated with ASD and providing comprehensive care. With the help of \$12 million in federal funding, the ATN is developing national standards for the medical treatment of ASD across 17 sites in the United States and Canada. The Autism Genome Project – a collaboration of 120 scientists from 19 countries – uses Autism Speaks genetic database (Autism Genetic Resource Exchange) and brain bank (Autism Tissue Program) to identify new genes that contribute to autism risk, leading to multiple discoveries that impact the understanding of the biology and treatment of autism. The Toddler Treatment Network and High Risk Baby below Siblings Research Consortium are collaborations of 23 scientists from 19 universities who have developed guidelines for early recognition of infants at risk and early intervention approaches for young toddlers

with autism. Autism Speaks funded the launch of the Interactive Autism Network (IAN), the first national online autism registry, which is accelerating autism research by linking more than 10,000 registered families to researchers nationwide. As part of its international development efforts, Autism Speaks launched the Global Autism Public Health Initiative (GAPH), an ambitious advocacy effort that aims to increase autism awareness, enhance capacity and explore unique opportunities in research, and improve service delivery worldwide. Through this effort, Autism Speaks supported the translation and adaptation of diagnostic instruments in languages spoken by 1.75 billion people across the globe. Great advances in the understanding of autism's biology have led Autism Speaks to dedicate increased emphasis to translational research. Their translational research program seeks to accelerate the pace at which basic scientific discoveries are translated into new and effective ways of diagnosing, and treating autism spectrum disorders. This includes "bench to bedside" investigations that move the most promising medicines and other interventions from the laboratory into clinical trials in real world settings such as hospitals, clinics and communities – with the goal of improving outcomes for individuals on the autism spectrum.

Awareness

Autism Speaks' award-winning "Learn the Signs" campaign with the Ad Council has received more than \$258 million in donated media and helped raise awareness of autism to unprecedented levels. Through collaboration between the State of Qatar and Autism Speaks, the UN sanctioned a World Autism Awareness Day to be celebrated in perpetuity on April 2, one of only three disease-specific awareness days of its kind. Autism Speaks celebrates World Autism Awareness Day through its "Light It Up Blue" initiative that has featured the illumination of major US and international landmarks in blue light, including the Empire State Building, Niagara Falls, and the Kingdom Tower in Riyadh, Saudi Arabia. Autism Speaks' web site, autismspeaks.org, has grown to be the most comprehensive and most visited website on autism with over 2.7 million visitors in 2010.

Walk Now for Autism Speaks awareness and fundraising events are held in more than 80 cities across North America, and more than 350,000 individuals participated in 2010.

Family Services

Autism Speaks has provided to families easily accessible and understandable tools and resources for the autism community. The 100 Day Kit – available in English and Spanish – provides a roadmap for newly diagnosed families on how to move forward effectively during the first 100 days following diagnosis. The Asperger/High-Functioning Autism Kit assists families in getting the critical information they need in the first 100 days after a diagnosis specific to Asperger syndrome. The School Community Tool Kit assists members of the school community in understanding and supporting students with autism. Most recently developed, the Transition Tool Kit is a guide to assist families on the journey from adolescence to adulthood. The Autism Video Glossary is a free web-based tool to help parents and professionals learn more about the early warning signs of autism. An online Resource Guide provides families with almost 30,000 resources on everything from diagnosis and treatment centers to autism-friendly barbers. Autism Speaks' Family Services Community Grants program has thus far funded nearly \$3 million to expand innovative and effective community services around the country for people with autism of all ages. The organization is a primary organizer of Advancing Futures for Adults with Autism, which is working to prioritize the needs for adults with autism in order to develop a national policy agenda.

Advocacy

Autism Speaks has played a leading role at the federal and state levels to advocate for legislation that benefits people with autism and their families. The Combating Autism Act of 2006 authorized nearly \$1 billion in autism research and support, and current efforts are focusing on reauthorizing and expanding research and service funding at the federal level. Among the organization's key goals for the next 5 years is to fight for legislation that

will end autism insurance discrimination in all 50 states, as well as at the federal level. Thirty-one states now require insurance companies to cover evidence-based medically necessary autism treatments, including behavioral health treatments, with legislation pending in about ten additional states. It also plans to work with the federal government to set a national policy agenda for services and support of adults with autism.

Major Activities

Research Grant Programs

Autism Speaks offers many types of grants that target critical areas of autism research. The goal is to facilitate and promote efforts that will produce significant findings to lead to discoveries of the causes and development of treatments and improvements in the lives of people with autism.

- *Pilot Research Grants* stimulate the exploration of new avenues of research through 2-year awards aimed at testing novel ideas related to autism. These grants serve to bring new investigators into the field and allow researchers to collect preliminary data, which can permit them to compete for larger grants in future.
- *Treatment Research Grants* address the urgent need to develop effective therapies to treat those living with the disorder today by supporting research focused on all aspects of treatment, including behavioral, psychosocial, biomedical, and technological interventions.
- *Basic and Clinical Research Grants* build upon established research in a broad range of autism-related areas. They provide researchers with larger awards in order to pursue leads that have already shown promise in pilot studies.
- *Dennis Weatherstone Predoctoral Fellowships* are awarded to support highly motivated graduate students with an interest in devoting their careers to autism research.
- *Postdoctoral Fellowships in Translational Autism Research* are designed to support promising, well-qualified postdoctoral scientists in their pursuit of research training that involves translation of biological discoveries toward

novel and more effective methods for treating or diagnosing ASD. This is accomplished by encouraging multidisciplinary collaboration among basic scientists, applied researchers, and clinicians.

- *Suzanne and Bob Wright Trailblazer Awards* are designed to accelerate the pace of autism science. In commemoration of Autism Speaks' fifth anniversary and to honor the organization's pioneering cofounders, the Trailblazer Award is designed to respond quickly in funding highly novel projects with the potential to be transformative and/or to overcome significant research roadblocks.

Science Initiatives

As important as individual grants, initiative projects give Autism Speaks a much more proactive role in promoting specific research. Initiatives frequently involve formation of collaborative research efforts, support of targeted research, organization of research meetings, and creation of research resources.

- The Autism Genome Project (AGP) is the largest study ever conducted to find the genes associated with inherited risk for autism. The ultimate goal is to enable doctors to biologically diagnose autism and researchers to develop universal medical treatments and a cure.
- The *International Autism Epidemiology Network (IAEN)* is an effort to understand the prevalence and causes of autism, particularly across diverse genetic and cultural settings. The activities of this network led to a multinational registry program to examine pre and perinatal factors associated with autism in the largest cohort of children with autism to date.
- The *Global Autism Public Health Initiative (GAPH)* aims to increase public and professional awareness of autism spectrum disorders worldwide, to enhance research expertise and international collaboration, and to improve service delivery in underserved populations.
- The *Environmental Factors in Autism Initiative* targets research that seeks to understand

and identify the potential role environmental factors play in triggering autism.

- The *Innovative Technology for Autism Initiative* was established to lead in the development of products that provide real world solutions to issues faced by those with autism, their families, educators, healthcare specialists, and researchers.
- The *High Risk Baby Siblings Research Consortium (BSRC)* aims to accelerate the understanding of the earliest markers of autism by bringing together the major research groups in the field to investigate infant siblings of children with ASD, including studying the heterogeneity of symptoms and developing best clinical practices.

Clinical Programs

Autism Speaks' clinical programs assist the research community in a variety of ways and include the following:

- The *Autism Genetic Resource Exchange (AGRE)* is a repository (gene bank) of genetic and clinical information from families with two or more members diagnosed with an ASD that is made available to autism researchers worldwide. For over 10 years, AGRE has accelerated the pace of autism research by collecting genetic and clinical data and providing it to researchers, allowing them to focus efforts on their investigations rather than data collection. www.agre.org
- The *Autism Tissue Program (ATP)* is dedicated to increasing and enhancing the availability of postmortem brain tissue to as many qualified scientists as possible to advance autism research. Brain tissue allows scientists to go far beyond the constraints of other technologies and study autism on both a cellular and molecular level. www.autismtissueprogram.org
- The *Autism Treatment Network (ATN)* is a network of hospitals and medical centers working together to improve the quality of care for individuals with autism. The clinicians in the ATN provide comprehensive, coordinated, multidisciplinary care to families in their communities, and are dedicated to establishing standards of care for autism that can be shared

across the wider medical community. www.autismspeaks.org/atn

- The *Autism Clinical Trials Network (ACTN)* is a collaboration of medical and research centers working together on clinical trials of promising pharmaceutical or nutritional treatments for autism. The ACTN approach enables sites to enroll children around the country in a single study, allowing sites to reach recruitment goals in a much shorter amount of time and accelerating progress toward scientifically proven treatments. www.autismspeaks.org/ctn
- The *Interactive Autism Network (IAN)* is an innovative online project designed to accelerate the pace of autism research by linking researchers and families. In addition, families of children with an ASD can share information in a secure online setting and become part of the nation's largest online research effort. www.ianproject.org

Autism Spectrum Addendum to the Anxiety Disorders Interview Schedule-Parent Interview

Connor M. Kerns
Department of Psychology, University of British Columbia, Vancouver, BC, Canada

Synonyms

[Anxiety disorders interview schedule \(ADIS\);](#)
[Autism spectrum addendum \(ASA\)](#)

Description

The Autism Spectrum Addendum (ASA) is a series of guidelines, prompts, and questions that can be woven into the Anxiety Disorders Interview Schedule-IV-Child/Parent (ADIS-IV-C/P; Silverman and Albano 1996), a semi-structured diagnostic interview of childhood anxiety disorders and related condition (e.g., obsessive-compulsive disorder [OCD], major depressive disorder, attention deficit hyperactivity disorder) to better tailor it for children with autism spectrum disorder (ASD). For brevity, we will refer to the combined tools as the ADIS/ASA. The purpose of the ASA is: (1) to provide systematic guidelines for differentiating potentially overlapping anxiety and autism spectrum symptoms, such as social avoidance, and (2) to capture distinct worries and fears that arise in ASD but do not fit traditional categories of anxiety as outlined in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, TR (DSM-IV-TR; American Psychological Association 2000), or the more recent, DSM, Fifth Edition (DSM-V; American Psychological Association 2013). The ADIS-IV-C/P assess for DSM anxiety disorders with a series of diagnostic modules. In each module, DSM criteria are queried with a mandatory set of questions, about which the interviewer may follow-up as needed to clarify a participant's meaning, ensure their understanding of the question, and gather more information. In addition, for modules in which symptoms are endorsed, interviewers provide clinician severity ratings (CSR) from 0 (not severe) to 8 (extremely severe), with 4 being the cut-off for diagnosis and 1–3 used to indicate subclinical symptoms. Typically, the ADIS-IV-C/P is administered to both children and parents and diagnoses are based on composite ratings, that is, the highest CSRs provided for each diagnostic module by either the parent or the child interviewer. Though having multiple informants is preferable whenever possible in clinical assessment, initial development of the ASA has focused on the parent interview – the ADIS-IV-P – given research suggesting that child report may be less reliable in children with ASD (Storch et al. 2012) or, in the case of children without communicative language, impossible to collect.

In the ADIS/ASA, the ADIS-IV-P is administered in its standard form with the ASA content woven in to guide interviewer's follow-up questions, systematically gather information important for differentiating anxiety and ASD symptoms, and gather information about distinct presentations of anxiety that may be reported. ASA content supports the assessment of Separation Anxiety Disorder, Social Anxiety Disorder, Specific Phobia, Generalized Anxiety Disorder and OCD. Though the ADIS-IV-P is designed to assess DSM-IV-TR anxiety disorders, it should be noted that the specific criteria for these disorders were not substantially altered in DSM-V (Kupfer 2015; APA 2000, 2013).

In addition to these DSM-consistent diagnoses, the ASA queries for distinct fears and worries that may arise in ASD, including fears of social situations that do not reflect a fear of negative evaluation (referred to as "other social fears"), uncommon phobias (e.g., fears of toilets, mechanical things, men with beards, specific songs), fears of change, and worries related to preoccupations. The ASA also assesses for compulsive behavior (e.g., insistence that doors remain closed or sleeves rolled up) that is associated with distress, but does not clearly have a compensatory function, as is the case for rituals and compulsions in OCD. These symptoms are referred to as Ambiguous OCD. Like the standard ADIS-IV-P modules, these other categories of anxiety, if reported, are assigned a CSR from 0 to 8, with 4 representing the cut off for clinically significant symptoms and 0–3 used for subclinical concerns.

Additional items designed to support differential diagnosis and the assessment of these distinct presentations include an expanded interpersonal relationships sections to assess children's attainment of reciprocal friendships, history of bullying, and levels of social motivation and social awareness. These items provide clinicians with a greater sense of whether social avoidance in a child with ASD may be attributable to social anxiety disorder, other social fears (i.e., fears related to nonverbal communication difficulties), or simply low social interest. They also allow clinicians to assess the extent to which fears of negative evaluation may be adaptive and proportionate rather than maladaptive and excessive (a requirement for

diagnosis). Additional differential diagnosis items include queries into levels of sensory sensitivity and perseverative thinking in each child, which are used to ensure that these ASD-related difficulties are considered and not misinterpreted as symptoms of specific phobia (e.g., phobia of loud sounds) or generalized anxiety. Each differential item is rated on a 0–3 scale, with 0 representing an absence of difficulties or deficits and 3 indicating significant difficulties.

Historical Background

Symptoms of anxiety have long been reported in children with ASD, so much so that anxiety is described as an associated feature of the disorder in the DSM-V and prior version (APA 2000, 2013) as well as the original case descriptions of ASD by Kanner (1943). Nonetheless, the diagnosis of co-occurring anxiety disorders in ASD is not straightforward, given that many symptoms of anxiety are also characteristic of ASD (e.g., social avoidance, ritualistic behavior, perseverative thinking, arousal dysregulation; Kems et al. 2016; Vasa et al. 2016). In addition, deficits in communication in ASD may complicate the assessment of anxiety symptoms, some of which are dependent on language (e.g., worries). Finally, a growing body of research suggests that children and adults with ASD experience fears and worries that are both similar and dissimilar to those of individuals in the general population (Adams et al. 2019; Den Houting et al. 2018; Halim et al. 2018; Kerns et al. 2014, 2017; Magiati et al. 2017; Scahill et al. 2019). Specific, distinct sources of fear include anxiety related to small changes in the environment, nonthreatening items, sounds, or sights (e.g., beards, glasses, specific songs), anxiety linked to a perseverative interests and anxiety related to difficulties understanding social cues and expectations. Whether the fears and worries of a child with ASD should be considered clinically significant as opposed to normative can also be difficult to determine given that the developmental level of children with ASD may not match their chronological age and because children with ASD often experience stressors, such as bullying and academic difficulties, about which some anxiety would be appropriate.

Given these challenges, it is perhaps unsurprising that estimates of the rates and associated characteristics of anxiety disorders in ASD have varied widely in the research literature (11–84% across studies) and even among studies employing diagnostic interviews (39–84%; Kerns and Kendall 2012; Van Steensel et al. 2011; White et al. 2009). This is likely due, in part, to inconsistency around the differential diagnosis, conceptualization, and measurement of anxiety disorders in ASD across these studies. The ADIS/ASA was developed to address this inconsistency, by providing a systematic and guided approach to differential diagnosis of anxiety in ASD and measuring distinct or ASD-related fears and anxieties as opposed to DSM-anxiety disorders alone. Notably, though a meta-analysis of studies assessing only DSM-consistent symptoms concluded that approximately 39.6% of youth with ASD present with clinically significant anxiety (Van Steensel et al. 2011), more recent studies suggest this rate may be closer to 63–69% when distinct as well as traditional fears are assessed (Kerns et al. 2014, 2020; Den Houting et al. 2018).

Psychometrics

The reliability and validity of an initial version of the ADIS/ASA was first examined in a sample of 59 youth, ages 7–17 years with ASD, who were recruited as part of a neuroimaging study of ASD (i.e., not selected for anxiety; Kerns et al. 2014). In this version, both the child and parent interviews were conducted and final diagnoses reflected the composite CSR from both reports. Support was found for the convergent and discriminant validity of the interview. Both traditional and distinct anxiety CSR were significantly correlated with other measures of anxiety, including the Screen for Child Anxiety and Related Emotional Disorders (SCARED; Birmaher et al. 1999) Total Score and Behavior Assessment System for Children-Second Edition Anxiety subscale (BASC-2; Reynolds and Kamphaus 2004). By comparison, neither traditional nor distinct anxiety CSR were significantly associated with externalizing behavior or daily living skills as measured by the BASC-2. Distinct

anxiety CSR, but not traditional anxiety CSR, were significantly associated with each other, but had distinct relationships to other measures of autism-related symptoms. Specifically, only distinct anxiety was significantly associated with higher levels of autism symptoms (Social Responsiveness Scale, Total Score; Constantino and Gruber 2012) and atypical behaviors (BASC-2 atypicality subscale). Inter-rater reliability, assessed in 35% of the sample, suggested good agreement between evaluators on both diagnoses (percent exact agreement: 95–100%) and CSR (*Intraclass Correlation [ICC]* = 0.89–0.99). Retest reliability, assessed in 25% of the sample, indicated that diagnoses (100% exact agreement) and CSR were also consistent over an approximately 2-week time period (0.88–1.00).

Results from this study were used to refine the parent version of the ASA to create the current tool, the psychometrics of which were examined in a new sample of 79 children ages 9–13 years with ASD and no more than mild intellectual impairments (IQ range: 68–143) who were seeking treatment for anxiety as part of a randomized clinical trial (Kerns et al. 2017). In contrast to Kerns et al. (2014), this sample included a larger proportion of children with ASD and co-occurring anxiety disorders, allowing for a more rigorous test of the inter-rater reliability of the different types of anxiety assessed by the ADIS/ASA modules and CSR. Findings again suggested good agreement between independent raters about both DSM-anxiety diagnoses (Cohen's Kappa [*K*] = 0.67–0.91) and CSR (*ICC* = 0.85–0.98) as well as the clinical significance (*K* = 0.77–0.90) and CSR (*ICC* = 0.87–0.95) of distinct anxieties. Support was also found for the discriminant validity of the ADIS/ASA, with partial support for convergent validity. In keeping with Kerns et al. (2014), neither ADIS/ASA traditional nor distinct anxiety CSR were significantly correlated with measures of parent-reported attention or aggression difficulties in the child (as measured by the Child Behavior Checklist; Achenbach et al. 2001). In addition, distinct but not traditional anxiety was associated with a measure of ASD severity (Autism Diagnostic Observation Schedule Comparison Score; Gotham et al. 2009). In contrast to Kerns et al. (2014), traditional but not distinct anxiety CSR were

associated with other measures of parent-reported anxiety (Child Behavior Checklist DSM Anxiety Subscale). Cumulatively these results suggest that the association of traditional anxiety measures and distinct anxiety may vary depending upon sample characteristics and recruitment methods.

Clinical Uses

The ADIS/ASA is designed to help clinicians determine whether a child with ASD meets criteria for a DSM anxiety disorder, other forms of clinically significant anxiety, and OCD. As it is a diagnostic tool, it should only be administered by those with or receiving training in child development and psychological evaluation. Given that administration is typically between 1.5 to 3 h (Mean = 105.36 min, Standard Deviation = 30.32 min; Kerns et al. 2017), the ADIS/ASA is not recommended as a primary or universal screening measure, but rather as a tool for differential diagnosis in children with complex case presentations or when precise clinical characterization or behavioral phenotyping is the goal. Importantly, information on the psychometric properties of the ADIS/ASA has only been published on samples of children with ASD between the ages of 7 and 17 years with no more than mild intellectual impairments. The ADIS/ASA may also provide a useful conceptual framework for clinicians assessing anxiety in preschoolers and children with ASD and more severe intellectual impairments; however, research to support its use in these populations is still ongoing. Similarly, though prior research suggests that the ADIS-IV-P is sensitive to changes in anxiety in children with ASD due to treatment (Reaven et al. 2012; Weiss et al. 2018), whether this also the case for the ADIS/ASA is being studied (see Kerns et al. 2016).

Description

The Autism Spectrum Rating Scales (ASRS) (Goldstein and Naglieri 2009) are designed to measure behaviors reported by parents and/or teachers

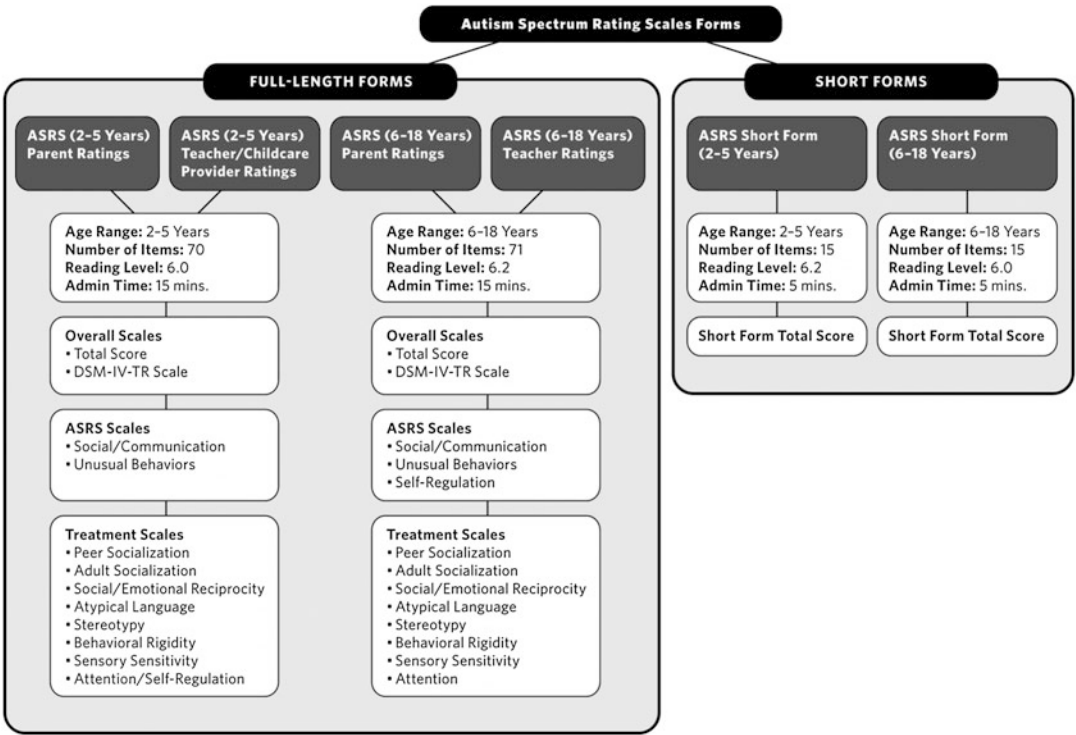

associated with autism spectrum disorders (ASDs) for children and youth aged 2 through 18 years. The ASRS can help guide diagnostic decisions and can be used during treatment planning, ongoing monitoring of response to intervention, and program evaluation. The ASRS includes items related to DSM-IV-TR autistic disorder, Asperger’s disorder, pervasive developmental disorder—not otherwise specified (PDD – NOS), and DSM 5 autism spectrum disorder. As recognition and prevalence of these conditions increase, the risk of over- and underdiagnosis increases in parallel. The need for a valid, reliable, and carefully crafted tool for assessment becomes paramount.

As illustrated in Fig. 1, the ASRS has full-length and short forms for both young children aged 2 to 5 years and youth aged 6–18 years. The full-length ASRS (2–5 years) comprises 70 items, and the full-length ASRS (6–18 years) consists of 71 items. There are separate parent (ASRS parent ratings) and teacher (ASRS teacher ratings) forms for both age groups. The ASRS short forms were developed by selecting the items that best differentiate

between nonclinical youth and youth diagnosed with ASD. The ASRS short form (2–5 years) and ASRS short form (6–18 years) both contain 15 items, and parents and teachers/caregivers complete the same form. All scales are set to the *T*-score metric, which has a normative mean of 50 and standard deviation of 10.

All of the ASRS forms are available in the MHS QuikScore format. The rater writes on the external layers of the form, and the results are transferred to a hidden scoring grid within the internal layers. The assessor then uses the internal layers for tabulating and profiling results. Each ASRS QuikScore form includes profile sheets, which are used to convert raw scores to *T*-scores and percentiles. These profile sheets also include a chart where scores can be plotted for a graphic display of the results. For individuals who wish to use software or online scoring, ASRS items are also provided in a response booklet format that does not include the scoring pages.

The ASRS can be completed and automatically scored online wherever an Internet connection is

Autism Spectrum Rating Scale, Fig. 1 ASRS Scales and Forms

available. Paper-and-pencil forms can also be scored online by entering responses from a paper-and-pencil administration into the online program. All ASRS forms can be scored using the scoring software by entering responses from a completed paper-and-pencil administration into the software program.

In some instances, the assessor may wish to obtain information about a group of youth instead of an individual. In a preschool or school setting, the ASRS can be used to screen a group of children to determine which children might require a full evaluation or to identify children who might benefit from additional support. The ASRS short forms have excellent reliability and validity, are good predictors of the ASRS total score, and were developed for screening purposes. High scores suggest that additional considerations are needed. For example, high scores on the short form might indicate the need for further examination with the full-length form, a more thorough evaluation, and/or some treatment to modify troubling behaviors.

Results from the ASRS can inform decisions about the effectiveness of a particular individual or group intervention. When used in a clinical setting, ASRS results can be collected at the beginning of an intervention and at several points throughout the intervention (in intervals of 4 weeks) in order to evaluate whether a particular program is associated with symptom improvement. In research studies, group data from the ASRS can be analyzed to determine whether change (pre- versus posttreatment or experimental treatment versus control group) is significant. Results from these types of evaluations can be helpful in supporting the need for the continuation of a treatment program or line of research.

ASRS reports can be obtained using the software or online scoring option. There are three report types for all of the ASRS forms: the interpretive report (provides detailed results from one administration), the comparative report (provides a multi-rater perspective by combining results from up to five different raters), and the progress monitoring report (provides an overview of change over time by combining results of up to four administrations from the same rater).

Historical Background

The ASRS development project encompassed 5 years (2004 to 2009), thousands of ratings by parents and teachers, intensive research, sophisticated statistical analyses, and multiple data collection sites. Development of the ASRS occurred in three phases: (1) conceptualization/initial planning, (2) pilot study, and (3) final scale construction (including the normative study). The ASRS was originally conceptualized as an assessment tool that would assess autism spectrum disorder (ASD) symptoms from early childhood through adolescence; therefore, the initial age range of the assessment was 2–18 years. Because of the importance of multi-informant assessment, it was determined from the onset that both parent and teacher forms would be created. Since great importance was placed on the ability to compare results across different raters, a decision was made to include identical items on both the parent and teacher forms.

A comprehensive review of current theory combined with literature on the assessment of ASDs, the DSM-IV-TR and ICD-10 diagnostic criteria, and the authors' experiences were used to determine the preliminary content structure. This structure guided item generation, and multiple items were developed to capture key components of each construct. A DSM-5 scale was added in 2013 as well as an accommodated scoring profile for nonverbal children in 2012.

Psychometric Data

Development of the final scale involved normative and clinical data collection, factor analyses to determine the factor structure of the forms, the creation of the total score, the DSM-IV-TR scale, and the treatment scales. The final scale construction began with the collection of normative and clinical data. The normative samples include 2,560 ratings (640 for the 2–5-year-olds rated by parents and teachers/childcare providers and 1,920 for the 6–18-year-olds also rated by parents and teachers). These samples include ratings of 40 males and 40 females at each age and are representative of the US population across several

demographic variables. The clinical samples include nearly 700 ratings of youth diagnosed with ASD and over 500 ratings of youth diagnosed with other clinical disorders (including delayed cognitive development, delayed communication development, ADHD, anxiety disorders, depressive disorders, and language disorders).

In order to examine the underlying factor structure of the ASRS items, data from both the normative and clinical samples were used in exploratory factor analyses (via principal axis extraction and direct oblimin rotation). Results of these analyses suggested that a two-factor model was most suitable for both the parent and teacher ASRS (2–5 years) forms, while a three-factor model was most suitable for the parent and teacher ASRS (6–18 years) forms. These factor-derived scales were labeled the “ASRS Scales” and include social/communication and unusual behaviors on all forms, as well as self-regulation on the ASRS (6–18 years).

In order to ensure that there was no redundancy in the scales, the ASRS Scale scores were intercorrelated (i.e., redundancy would be implied if the correlations were very high) on the total sample (i.e., the normative plus the clinical sample). Results indicated that the scale intercorrelations met theoretical expectations (i.e., they were moderate in size), providing additional support for the multidimensionality of the measure.

Clinical Uses

The ASRS can be used as an aid in the diagnostic process. Standardized scores from the ASRS allow the assessor to effectively compare an individual to a norm group in an objective and reliable manner. Scores can be integrated with other information to form a complete picture of the individual. When used in combination with other assessment information, results from the ASRS can help guide diagnostic decisions, treatment planning, and ongoing monitoring of response to intervention. The ASRS can also be used to evaluate the effectiveness of a treatment program for a child with ASD.

The ASRS can also be a tool for researchers in a variety of settings and research protocols. There

are several advantages the ASRS offers to researchers. First, the scales were carefully developed to measure a wide spectrum of behaviors associated with ASD. Second, the various scales included provide scores based upon a normative sample aged 2–18 years based on a diverse, representative group of individuals. Third, the scales included on the ASRS have demonstrated reliability, which is particularly important in correlational studies, and validity, which is particularly important for both internal and external validities of any research project. Fourth, the psychometric qualities of the scale are well documented in this manual. Fifth, comparisons to other instruments are easier due to the availability of standard scores.

The ASRS was carefully developed and researched to provide the most useful set of items for ASD identification and intervention. Any rating scale has inherent limitations; however, when used appropriately, the ASRS is a useful tool in the entire process of defining the problem, eliciting information from parents and teachers, planning treatment and intervention, and measuring treatment outcome in ASD.

Autism Theory

Nick Chown¹ and Luke Beardon²

¹Palau-solità i Plegamans, Lliçà de Vall, Barcelona, Spain

²The Autism Centre, Institute of Education, Sheffield Hallam University, Sheffield, South Yorkshire, UK

Definition

A multitude of theories have attempted to explain certain cognitive characteristics of autism. Although adherents of some of these theories (such as theory of mind) may once have contended that their particular theory could fully

explain autism, it is generally considered nowadays that an explanation of autism requires a synthesis of theory. Three theories – theory of mind, executive (dys)functioning, and central coherence – assume a special place in the pantheon of cognitive autism theory. In the limited space available, we provide a brief introduction to these three “mainstream” theories together with various other “alternative” theories including the single attention/monotropism hypothesis of Murray et al. (2005) which, arguably, explains more characteristics of autism than any other theory.

More than 70 years after Asperger and Kanner first wrote about autism, there is still no definitive autism theory. We doubt there will ever be a full theoretical explanation of *any* neurotype because of the complexities involved. But we also firmly believe that the theories we introduce here are of great value in describing characteristics of autism that can help autistic individuals to understand themselves better and help those who live with and/or support autistic individuals to understand autism. Improved understanding should lead to better interventions and other support for autistic people.

Cognitive Theories of Autism

Theory of Mind

The theory of mind (ToM) is one of the three “big ideas” of autism theory. ToM refers to an individual’s ability to attribute mental states to themselves and to others (Frith and Happé 1999). Put in another way, ToM is the everyday folk psychology that people use to make sense of other people’s behavior by hypothesizing about the beliefs, desires, and feelings that motivate actions. ToM is a way of describing the need for individuals to develop an understanding that objects and other persons have separate existence, that other persons have their own mental state that differs from theirs, and be able to “put on the shoes” of another person mentally. Predicting another person’s likely behavior can be likened to developing a hypothesis about expected behavior. ToM is often referred to as “mind reading” (Baron-Cohen 1995) although it involves the use of

sensory stimuli to guess the mental state of others and there can be no direct access to another person’s mind in the sense of a psychic power!.

An example should better explain the nature of ToM difficulties. It relates to a 16-year-old boy with Asperger syndrome who we will call James. James cannot see things from the perspective of his 8-year-old sister. Like other children of her age, his sister makes statements and asks questions that he finds ridiculous such as: “I want to go to the moon on holiday” and “I’m going to have 20 children when I grow up.” James cannot ignore things like this, agree, or join in on the same line of thought, as he cannot see these comments for what they are, the things a child much younger than him will say. Instead he has to ridicule what she says and explain in detail why it is impossible for her to go to the moon and that it is extremely unlikely that she will ever have so many children. Naturally, this upsets his sister and can make family life stressful. No amount of parental explanation makes any difference to James; his limited ToM prevents him from putting himself in his sister’s shoes and interpreting her comments from her perspective instead of his own.

ToM probably developed in human beings relatively recently (thousands of years ago) to enable us to cope with a social environment that was becoming increasingly complex as the species developed. Social interaction aided by ToM will have had benefits for both reproduction and survival. A newborn child has no understanding that the world exists independently of itself. The child is unable to form mental representations of persons or objects. At this earliest stage of its life, an object exists for the child only while it is in sight and ceases to exist when out of sight. As the child grows, its developing ToM enables it to form mental representations of other objects and persons, and, later on, it learns that other persons have a thinking existence of their own (Frith and Happé 1999). The ability of typically developing children to evaluate the thoughts, emotions, intentions, and beliefs of others grows over time. While major advances in a child’s ToM take place during preschool years, this ability continues to develop throughout childhood and even into adolescence and adulthood. An autistic young person’s ToM

ability may, at least partially, “catch up” with that of their typically developing peers during their adolescence and adulthood.

Executive (Dys)Functioning

A further theory that attempts to explain aspects of autism is known as executive (dys)functioning. Although executive function (EF) was not defined until the 1970s, the beginnings of this concept date right back to a railway accident in 1840. A man called Phineas Gage – sometimes known as “neuroscience’s most famous patient” – was a railway construction foreman in the USA leading a team cutting a railway bed in the state of Vermont. He suffered a very serious head injury when a premature explosion sent a tamping iron – an iron rod – flying in his direction. The tamping iron was nearly 4 feet long, 1 ¼ in. in diameter, and weighed 13 ¼ pounds. It “penetrated Gage’s left cheek, ripped into his brain, and exited through his skull, landing several dozen feet away.” The rod destroyed a large part of Gage’s left frontal lobe. He survived this dreadful accident, but the severe injuries caused a change in his personality and behavior. He became “disinhibited” or “hyperactive,” as is often found in persons with damage to the prefrontal cortex. It was Gage’s accident in particular that caused the medical profession to consider the role of the frontal lobes in what we now call EF, although real progress in developing this concept did not begin until the 1950s.

Delis (2012, p. 14) writes that “Neither a single ability nor a comprehensive definition fully captures the conceptual scope of executive functions: rather, executive functioning is the sum product of a collection of higher level skills that converge to enable an individual to adapt and thrive in complex psychosocial environments.” Others have defined EF as “an overarching term that refers to mental control processes that enable physical, cognitive, and emotional self-control” (Corbett et al. 2009, p. 210) and “several abilities for preparing and engaging in complex organized behaviour” (Macintosh and Dissanayake 2004, p. 426). Although the main components of EF have yet to be established definitively, they are likely to

include formation of abstract concepts, planning, focusing and sustaining attention, shifting focus, and working memory (Macintosh and Dissanayake 2004; Attwood 1998).

Many studies have demonstrated that persons on the autism spectrum often experience difficulties with executive functioning. However, although these difficulties can be pervasive, they are not all necessarily universal in autism. It is also the case that some executive function processes are often less likely to be affected in autism than others (e.g., difficulty with planning is more common than an inability to inhibit impulsive behavior).

Central Coherence Theory

The third main cognitive theory of autism is the theory of central coherence (CC). This theory, developed by Uta Frith and Francesca Happé (1994), attempts to explain why persons with autism exhibit particular strengths in addition to weaknesses. CC is the ability to see the gist – the so-called big picture – rather than just the detail of which something is comprised. CC theory originally proposed that persons with autism will have what Happé and Frith called weak CC in that there will be a tendency for them to focus on the detail at the expense of being able to see things in the round and generalize. Tony Attwood describes weak CC as being “remarkably good at attending to detail but (having) a weakness in perceiving and understanding the overall picture, or gist” (Attwood 1998, p. 241). In accordance with this theory, it should be possible to see strengths in the manipulation of detail in autism in addition to difficulties in forming a holistic picture from the detail.

In a later development of their CC theory, Happé and Frith (2006) contend that there is a *preference* for detail in autism rather than a weakness in CC. They now write of a difference in information processing style in autism, with concomitant strengths, rather than impairment. Happé and Frith also argue that there is a continuum of CC along which all people fit, with autistic individuals lying at the “detail” end of the continuum.

Single Attention/Monotropism

Murray et al. (2005) have investigated the current diagnostic criteria for autism in the light of their theory that autism has its foundation in what they describe as single attention/monotropism. These authors hypothesize that a limited amount of attention available to all people – autistic or not – plays a fundamental part in day-to-day life and is largely a matter of inheritance. They argue that differences in the spread of attention available to individuals are normally distributed between a wide spread of attention over many interests at one end of the distribution and a much narrower focus of attention on only a few interests at the opposite end. Importantly, they regard the “restricted range of interests” referred to in the DSM-IV and ICD-10 diagnostic criteria, and which they call monotropism (A colleague has suggested that the term “monotropism” would be more appropriate for someone with a *single* interest rather than few interests.), as being central to autism.

Instead of a preference for detail over wholes, Murray, Lesser, and Lawson argue for a state of heightened (hyper)awareness inside an “attention tunnel” and lessened (hypo)awareness outside this tunnel. They consider that their proposed tunnel effect also causes the hypersensitivity and hyposensitivity to sensory experiences often seen in autism. Their proposal is that autistic people are hypersensitive within the attention tunnel and hyposensitive outside the tunnel. The single attention/monotropism theory is one of the few that seeks to explain both cognitive *and* sensory differences in autism. The “big three” theories say nothing about the sensory issues so often associated with autism. It is our belief that good autism theory, or theory synthesis, must be capable of explaining the cognitive *and* sensory differences.

Joint Attention

Joint attention refers to a group of nonverbal behaviors for communicating with another person about something, usually an object. Joint attention includes altering eye gaze between the other person and the object and the use of gestures such as pointing. There is no definitive definition of joint

attention but a number of “competing” attempts to set out what it involves. To further complicate matters, there are two aspects of joint attention to be considered, *initiation* of joint attention and *response* to joint attention. Initiation of joint attention refers to a child’s action in seeking the attention of another person. A child’s response to another person’s seeking to gain their attention – which could be either a shift in the gaze of the other person’s eyes or a pointing action – is known as response to joint attention. Joint attention is important because, in a typically developing child, it is associated with the child’s development of a further concept known as intentional communication which has been referred to as understanding and controlling the transfer of information between individual human beings (or members of other species). A communication must involve a “sender,” a recipient, and signals conveying information between sender and recipient. Woodruff and Premack (1979, p. 334) write that communication is intentional if “the sender (i) appreciates the fact that his behavior transmits information, (ii) recognizes that the recipient also knows that his behaviour is informative, and (iii) is able to choose from a set of alternatives that course of action (or inaction) which will provide (or suppress) a given bit of information.” While in any communication there is a transfer of information between sender and recipient, they stress that in intentional communication, the transfer is purposive because the sender knows that their communication may have a particular effect on the recipient and that effect is sought by the sender.

At some point, the young child begins to understand that another person can help them to achieve some end and that they can communicate their wish to that other person by sending signals. As the child develops, their communication increasingly becomes intentional. It is generally considered that a typically developing child learns between the ages of 6 and 9 months that a particular communicative action or signal has the same effect each time. Whether or not joint attention is a type, or a characteristic, of intentional communication, it is regarded as crucial in developmental terms because without it, functional speech would

not be developed by a child. It is argued that in autism, there is either a delay in the development of the joint attention behaviors associated with intentional communication or such behaviors are not developed at all.

Empathizing/Systemizing Theory

Empathizing involves the identification of another person's emotions and thoughts, the ability to respond to emotions and thoughts appropriately, and the ability to predict a person's behavior. Empathizing has been likened to folk psychology which is the common sense ability of human beings to explain and predict behavior and mental states in other human beings. According to Baron-Cohen (2002, p.248), systemizing "is the drive to analyse the variables in a system, to derive the underlying rules that govern the behavior of a system . . . Systemizing allows you to predict the behavior of a *system*, and to control it." Systemizing skills include mathematical reasoning, mental rotation, mechanical reasoning, and spatial visualization. Systemizing has been compared to folk physics, which is the untrained understanding of basic physical phenomena by human beings. Research into sex differences in cognition has led to hypotheses that women are better than men at empathizing but that men are better than women at systemizing. The realization that persons with autism appear to have difficulty empathizing with other people in some cases, but may also exhibit strong systemizing skills, has caused some scholars to wonder if there is any connection between autism and a person's gender. It is Baron-Cohen's contention that a strong tendency to systemize and weak ability to empathize should be seen in autism. Because he thinks that systemizing is stronger and empathizing weaker in autism than in typically developing men, he has gone on to argue that autism is an example of what he refers to as an "extreme male brain."

Interaction Theory

In a challenge to "theory of mind" through claiming that direct access to other minds is not just possible but is the primary means by which individuals understand what another person is thinking, Shaun Gallagher relies on the

developmental psychological concepts of "primary intersubjectivity" and "secondary intersubjectivity." He writes of primary intersubjectivity that "By the end of the first year of life, infants are capable of a non-mentalistic, *perceptually-based* embodied understanding of the intentions and dispositions of other persons" (Gallagher 2008, p. 166, our italics) and that "secondary intersubjectivity builds on these primary perceptual and interactive capabilities . . . when infants start to recognize *context* as significant" (ibid., p. 166, our italics). He goes on to state that many theorists regard "the capabilities of primary and secondary intersubjectivity to be *precursors* to full-blown ToM" (ibid., p. 166, author's italics) in the sense that fully fledged ToM either builds on or replaces primary and secondary intersubjectivity. However, in his opinion "adult phenomenology attests to the continued role of primary and secondary intersubjectivity in our everyday understanding of and interaction with others" (ibid., p.166), quoting Scheler and Wittgenstein in his defense and writing that "Psychologists provide important empirical evidence that our everyday adult interaction is primarily *perceptual* and *contextual*" (ibid., p. 167, our italics). In other words, he considers that direct access to other minds is achieved by means of perception of facial expressions and body language in the light of the context in which the person does the perceiving. Tony Wootton (2002, p. 92) writes that "the pattern of [reduced] interactional involvement displayed by the autistic child will have as its corollary a radically diminished acquaintance with the practice of taking other people's views into account."

Narrative Practice Hypothesis

As previously stated, folk psychology, or commonsense psychology, is the natural capacity to explain and predict the behavior and mental states of other people. Daniel Hutto is sure that there is no need for an innate, hardwired theory of mind ability in human beings because typically developing individuals develop an understanding of folk psychology through continuous exposure during the formative years to stories that teach them about folk psychological practice. He puts it this way: "Encounters with narratives about

those who act for reasons best explain the origins of folk psychological (FP) abilities, both phylogenetically and ontogenetically. Such stories familiarize us with the forms and norms of folk psychology. This is the core claim of the Narrative Practice Hypothesis” (Hutto 2007, pp. 47–48).

Sensorially Disturbed Interaction Hypothesis

Victoria McGeer (2001, p. 129) proposes that sensory disturbances may lie at the heart of autism (as well as deafness and blindness) in that “Being excluded from the regulative influences of other people, autistics will not develop habits of agency that conform to shared norms of what it is to experience, think and act in recognizably normal ways” – which, in autism, could account for a failure to develop non-autistic social understanding [McGeer uses the term psycho-practical expertise] – as well-being “cast back on their own resources for managing their sensory experiences perhaps by reducing, repeating or drowning out incoming sensory stimuli in ways they can control” (ibid., p. 129). This could account for a range of typically autistic symptoms such as repetitive and self-stimulatory behaviors. McGeer writes that her speculations suggest that “becoming minded as others are minded, and sharing thereby in the advantages of normal psychological knowing, may finally depend on something as basic as having sensory access to others in a way that makes possible their regulative influence on us as developing children” (ibid., p. 129) which, if correct, would reconcile the focus of autistic autobiographical accounts of sensory sensitivities with the focus of non-autistic clinicians and researchers of autism on the social difficulties seen in autism.

Time-Parsing Deficit Hypothesis

Jill Boucher (2003, p. 250) refers to the fact that “An earlier hypothesis concerning the psychological cause(s) of language impairment in autism suggested that there is a fundamental deficit in the ability to process transient, sequential stimuli (i.e. stimuli with a temporal dimension) such as speech or manual signing,” which she attempted to revive in the slightly different form of a “time-parsing deficit.” With this theory of autistic language impairment, Boucher claimed that autism

involves varying levels of difficulty in the understanding of conversation exchanges (or signing) in real time “which contributes to the linguistic aspects of their pragmatic impairment” (ibid., p. 250). She considers that the extent of the difficulty in parsing conversation is dependent on where a person lies on the autism spectrum.

Enactive Mind Hypothesis

The enactive mind hypothesis is more of a theoretical framework for understanding autism than an actual theory of autism with Klin et al. writing of their hypothesis as “a framework different from the prevailing computational models of social cognitive development” (Klin et al. 2003, p. 357) involving “disembodied cognition” where cognition and action are separate. The key aspect of the enactive mind hypothesis is that, instead of a child’s mind consisting of certain innate capabilities which are gradually given rein, the mind is an “*active mind* that sets out to make sense of the social environment and that changes itself as a result of this interaction” (ibid., p. 348, our italics). Unlike the disembodied cognition associated with computational models, with an active mind, cognition and action are inextricably linked in the typically developing child *but apparently not in the autistic child*. The alternative framework is centered around:

a different set of social cognitive phenomena, for example people’s predispositions to orient to salient social stimuli, to naturally seek to impose social meaning on what they see and hear, to differentiate what is relevant from what is not, and to be intrinsically motivated to solve a social problem once such a problem is identified. [Their framework] is called EM in order to highlight the *central role of motivational predispositions to respond to social stimuli* and a developmental process in which social cognition results from social action. (ibid., pp. 347/348, our italics)

Enhanced Perceptual Functioning Model

Laurent Mottron and his team have proposed a perception-based model of autism described as the “enhanced perceptual functioning model” along with a set of eight principles of autistic perception (Mottron and Burack 2001; Mottron et al. 2006). The latest version of the enhanced

perceptual functioning model takes account of the researchers' realization "that a *primary* superiority in perceptual analysis could possibly underlie both local biases in hierarchical perception and construction, and exceptionally accurate reproduction of surface properties of the world, like 3-D perspective or absolute pitch values in savants" (Mottron et al. 2006, p. 28, authors' italics). In developing their model, Mottron et al. retained the concept of local bias from the weak central coherence theory (attributing it to superior perceptual functioning in autism) but regarding it as "mandatory" in autism in opposition to Frith and Happé's view of local bias as a cognitive preference.

Future Directions

After many decades of research to explain cognition in autism, there is still no definitive explanation or theory. But some theory does explain aspects of autism and has led to an improved understanding of what it is to be autistic and what needs to be done to support autistic individuals in the community. The vast majority of research into autism continues to be focused on what increasingly appears to be a fruitless search for what causes it. Such research is also potentially dangerous given the risks of it leading to susceptibility testing, genetic engineering, or even full-blown eugenics. Other researchers consider that the primary focus of autism research should be on identifying interventions, and other means of support, to improve the well-being of autistic individuals and their lived experience in a non-autistic world.

There is a distinct tendency for researchers involved in the development of interventions in autism to base their work solely on empirical evidence rather than on evidence *and* theory (Chown 2015). It would seem entirely appropriate for intervention researchers to take account of theories which provide an understanding of autistic cognition in connection with both the design and implementation of their interventions (as is the case with the highly successful Social

Stories™ intervention) or at least explain why they have not done so. Researchers in the intervention field would do well to consider theory and either explicitly include some form of *theoretical justification analysis* in their reporting alongside empirical findings or explain why their proposals require no theoretical justification.

Anecdotal evidence suggests that research into autism causation does not appear to have been as severely affected by austerity measures as has other autism research and diagnosis and support for autistic people. (A London Borough recently attempted to place a limit on the number of persons permitted to receive a diagnosis of autism in their part of the capital in order to meet budget cuts.) Given the commercial and other considerations that drive much autism research, one can only hope that governments will take increasing heed of the full range of views on this subject, and a leading role, so that research priorities cease to be so biased.

Autism Traits and Parenting

Cheryl Dissanayake, Amanda Richdale and
Natasha Kolivas

Olga Tennison Autism Research Centre,
La Trobe University, Melbourne, VIC, Australia

Definition

Raising children and providing them with protection and care in order to ensure their healthy social, emotional, cognitive, and physical development into adulthood are a critical task of parents. As parenting is known to impact children’s developmental outcomes, examining parenting in the context of autism is an important focus of inquiry.

Historical Background

Little remains known about the lives of adults with autism (Howlin and Magiati 2017), including parenting children. As parenting practices and parenting style are related to the developmental and psychological outcomes of children (Belsky and de Haan 2011), being autistic or having autism traits has the potential to influence parenting.

Autism is associated with difficulties in social communication and social reciprocity, including social-emotional difficulties (American Psychiatric Association (APA) 2013) which can impact the quality of social interactions. Social-cognitive difficulties are also common, including difficulties in taking another’s mental perspective, important in sensitive and responsive parenting (e.g., Laranjo et al. 2008). Furthermore, mental health, specifically depression and anxiety, can influence parenting practices (Berg-Nielsen et al. 2002), with individuals with autism and higher autism traits commonly reporting poorer mental health (Ingersoll and Hambrick 2011; Sucksmith et al. 2011). Good parenting also involves consistency and routine, with

predictability being important in giving children a sense of control, a feature also preferred by those with autism. Thus, much of what is known about both autism and parenting suggests this relationship is an important one to examine, particularly with regard to identifying parenting difficulties and needs that may require support. This understanding can lead to the development of methods to enhance and support parenting outcomes.

Current Knowledge

Only three studies to date have examined parenting with autism. Studying parents with subthreshold traits of autism (as measured by the Autism Spectrum Quotient, AQ; Baron-Cohen et al. 2001), van Steijn et al. (2013) found that mothers with high autism traits use a more permissive parenting style (which is high in warmth but low in control, unlike the optimal authoritative parenting style which is high in both) with their typically developing (TD) child compared to their child with a diagnosis of autism spectrum disorder (ASD). Interestingly, in fathers, it was their ADHD characteristics, not autism traits, that were related to difficulties in parenting of both their affected and unaffected children.

Lau et al. (2016) examined parenting efficacy (rather than parenting style) in mothers and fathers with and without an ASD diagnosis who were raising a child with ASD. They found that while fathers with a diagnosis of ASD reported being less efficacious in their parenting (as measured by the Parenting Sense of Competence scale, PSOC; Johnston and Mash 1989), mothers who had a diagnosis did not differ in their parenting efficacy from mothers without a diagnosis. However, children with a diagnosis of ASD may be difficult to parent because of their characteristics, and, as such, it is impossible to determine (in a cross-sectional study) whether any difficulties in parenting competence observed are due to the child's or the parent's autism traits.

Dissanayake et al. (2019) examined whether autism traits (as measured by the AQ) are uniquely related to parenting a TD child, over

and above other demographic and psychological factors, including the parent's own parenting history. While all parents had a child with ASD, their parenting was examined in relation to the TD child they were raising. None of the demographic variables, nor parenting history, played a role in the relationship between autism traits and the parenting variables studied. However, parental well-being, as measured by the Depression Anxiety and Stress Scale (DASS-21; Lovibond and Lovibond 1995), did contribute to parenting outcomes; thus although a relationship was found between autism traits and satisfaction in the parenting role, with higher traits associated with lower parenting satisfaction, when psychological well-being was accounted for, autism traits did not contribute uniquely to the model. Moreover, autism traits were not related to parenting efficacy. Given that the majority of participants in this study were mothers, this latter finding is consistent with Lau et al.'s (2016) finding that mothers with an ASD diagnosis did not differ in their parenting efficacy from mothers without ASD, although it should be noted that unlike in Dissanayake et al., their findings relate to parenting a child with ASD.

Dissanayake et al. (2019) found that autism traits were associated with parenting difficulties and some aspects of the parent-child relationship (as measured using the Parent-Child Relationship Inventory, PCRI; Gerard 1994) when raising a TD child. Autism traits were negatively related to three of the seven factors examined, with higher traits associated with less perceived enjoyment and fulfilment in the parent-child relationship (*Satisfaction*) and the level of interaction with the child (*Involvement*). As social interaction difficulties (APA 2013) are a core feature of ASD, it is not unexpected that individuals with high autism traits will experience more difficulty interacting with others, including members of their own family. Interestingly, autism traits were not related to other aspects of the parent-child relationship (including *Communication*, *Limit-setting*, *Autonomy*, and *Role Orientation*).

Autism traits were found to be associated with an increase in overall parenting difficulties, as measured by a Parenting Needs Questionnaire

(PNQ) developed by the study authors (Dissanayake et al. 2019). Psychological well-being was also related to parenting difficulties. However, autism traits were also uniquely related to parenting difficulties in all but two parenting domains. Parents with high autism traits reported more difficulties in the subscales of *Modeling/Teaching Behaviors*, *Understanding Needs*, *Emotion Control*, *Attention/Connection*, *Spontaneity*, and *Sensory Issues* compared to parents with low autism traits. Parent with high traits reported moderate difficulties regulating their emotion during parenting situations, and connecting with, or maintaining attention on their child during interactions. They reported more difficulties in modeling and teaching their child behaviors, understanding the needs of their child, being spontaneous in parenting situations, and coping with sensory stimuli around their child. As the development of the subscales of the PNQ was informed by parents who had ASD, it is perhaps unsurprising that those with high autism traits found difficulties in each of these areas.

There were, however, no differences observed in the *Affection Subscale of the PNQ*, indicating that parents with high autism traits do not find it more difficult giving and receiving affection from their child. This finding accords with research findings that both younger and older children with ASD are attached to their parents in the same way as are TD children (Chandler and Dissanayake 2014; Dissanayake and Crossley 1996; Dissanayake and Sigman 2000). The *Danger Awareness Subscale* also failed to differentiate parents with high and low traits, suggesting that these parents do not have difficulty anticipating dangers on behalf of their TD child. Showing and receiving affection and keeping children out of harm's way are critical aspects of parenting which appear to not be related to the presence of high autism traits.

Future Directions

The studies reviewed above on parenting children with and without autism when parents have either a diagnosis of ASD or high autism traits

themselves have identified specific aspects of parenting that may benefit from targeted support which can assist these parents prosper in their parenting role. It is likely that the wealth of available parenting resources will not address the specific needs of parents with high autism traits as the majority of these resources are developed for parents without additional needs, although there are available resources for parents raising children with additional needs. Thus, just as there is a paucity of research on the parents with ASD/high autism traits, there is a lack of parenting resources for them. However, a first step to providing information and resources needed for these parents from which they may benefit is available here: <https://www.amaze.org.au/2017/05/ceo-proud-of-our-new-parenting-skills-guide/>

The few studies to date on parenting with ASD/autism traits have been informed by the parenting literature, where research has been undertaken within the general population. Hence, the specific strengths that autistic parents may bring into their parenting role have not been a focus of study and should be examined in future research. It is also important to focus on the outcomes of the children who are the target of parenting, be they autistic or otherwise. Given the findings presented here that autism traits are related to both parenting abilities and difficulties, it is necessary to examine the positive and/or negative impacts, if any, on children's developmental outcomes.

Autism: Social Communication Disorder

Scott Luther James Jackson

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

Pragmatic communication disorder; Pragmatic language disorder; Pragmatic language impairment; Semantic pragmatic deficit disorder; Semantic pragmatic deficit syndrome; Semantic pragmatic language disorder; Social pragmatic communication disorder

Short Description or Definition

In more than 70 years since its first clinical descriptions, conceptualizing autism as a diagnostic category has been an ever-evolving and challenging process due to the broad heterogeneity that exists within this disorder. With the more narrow and rigid diagnostic criteria for autism spectrum disorder (ASD), as described in the DSM-5 (APA 2013), a new diagnostic classification was introduced in an attempt to account for individuals with marked impairments in social and communicative abilities but who fail to meet DSM-5 criteria for ASD: social communication disorder (SCD).

SCD, sometimes referred to as social pragmatic communication disorder, is defined by primary impairments in the pragmatic aspects of

verbal and nonverbal social communication. Specifically, those with SCD will present with significant difficulties interpreting meaning from social cues and adapting their communicative efforts to match social contexts (e.g. following conversation rules, modifying language for different situations or audiences, inferring meaning based on context).

Categorization

Clinical reports on disorders of pragmatic communication were first published in the 1980s (Bishop and Rosenbloom 1987; Rapin and Allen 1983) and described children who possessed relatively unimpaired vocabulary, grammar, and word structure but presented with significant difficulties utilizing and comprehending changes in language based on social contexts (see Semantic Pragmatic Disorder and Pragmatic Language Impairment). Symptomology overlap between these disorders and the social communicative characteristics of ASD were recognized from an early stage. As such, it was common for individuals with these disorders to receive diagnostic labels of Asperger's syndrome or PDD-NOS/unspecified (Bishop 1989).

In the DSM-5, SCD is categorized as a communication disorder along with childhood-onset fluency disorder, language disorder, and speech sound disorder, in the broader domain of neurodevelopmental disorders (the same domain as ASD). Outside the USA (particularly in the UK), the impairments which characterize SCD are approximately equivalent to a condition known as pragmatic language impairment (PLI). Relatedly, though PLI is not included as a diagnostic category in the DSM-5, it is reportedly going to be included in the upcoming ICD-11 as a language disorder (Baird and Norbury 2016). Despite the differences in labels, it is suggested that these two disorders will approximately encompass the same behavioral phenotype and will provide a diagnosis for individuals with the social communicative impairments of ASD but who lack the restricted interest and repetitive behavior characteristics of that disorder.

Epidemiology

As social communication disorder was only introduced as a diagnostic category with the release of the DSM-5 in 2013, epidemiological studies remain rare and limited in scope. Estimates on the prevalence and incidence of SCD, therefore, are still in preliminary stages. Based on the available literature, depending on which diagnostic manual you use, it is estimated that 8.25–15% (DSM-IV-TR) or 19% (ICD-10R) of individuals who would have previously met diagnostic criteria for a pervasive developmental disorder (PDD) would meet DSM-5 criteria for SCD (Kim et al. 2014; Wilson et al. 2013). These studies further noted that the PDD diagnostic subtypes with the greatest incidence of transferring to a SCD diagnosis based on DSM-5 criteria were Asperger's syndrome (6–15%) and PDD-NOS/unspecified (30–32%).

Only Kim et al. (2014) have produced population and gender prevalence estimates for SCD thus far in the extant literature. The findings of their study suggest that SCD has approximately a 0.5% prevalence rate, with a slightly greater occurrence in males than females (1.3:1 sex ratio). However, additional research on this topic (including cross-cultural examinations) will need to be conducted before the actual prevalence of SCD becomes clear.

Natural History, Prognostic Factors, and Outcomes

It is expected that the onset of symptoms associated with SCD will occur during the developmental stages of early childhood, with notable deficits emerging between age 4 and 5 years. For some, however, impairments may not become apparent until later years when social communicative demands eventually exceed the individuals' abilities. Again, due to the relatively new nature of this diagnostic label, there is limited knowledge available with regard to prognostic factors and outcomes.

According to the DSM-5, risk and prognostic factors associated with SCD include familial

history of other communication disorders, specific learning disorder, or ASD (APA 2013). Based on findings with populations with similar pragmatic language communication deficits (i.e., pragmatic language impairment), it can be inferred that some children with SCD will demonstrate improvements in their pragmatic abilities over time (Swineford et al. 2014). However, it is likely that for most, these difficulties will persist into adulthood, and while individuals with SCD may find success academically and reach levels of independence, these lasting communicative deficits are likely to effect the development of meaningful social and romantic relationships (Whitehouse et al. 2009).

Clinical Expression and Pathophysiology

Clinical expression of SCD involves persistent impairments in social communicative abilities that have been present from early development (though may not be apparent until later in life) and result in significant social, academic, and/or occupational limitations for the individual (APA 2013). Specifically, a diagnosis of SCD requires the presence of difficulties in the following areas of verbal and nonverbal communication:

- Utilizing communication for social reasons (e.g., social greetings, joint attention)
- Altering communication to fit social contexts (e.g., adjusting prosody and/or language depending on the setting)
- Following conversational rules (e.g., turn taking, staying on topic)
- Interpreting ambiguous or nonliteral language (e.g., metaphors, idioms)

The manner in which these impairments will present in an individual will depend on their age and the severity of their social and communicative difficulties. Elleseff (2015) details potential areas of difficulty that may be present in individuals at *initial*, *intermediate*, and *advanced* stages of social communicative development:

Initial: During this early stage, impairments may manifest as limitations in communicative

initiation, attention, and understanding of basic rules or conventions.

Intermediate: For those who progress beyond the above stages of social communicative development, impairments may instead present as difficulties with higher-order skills. Potential areas of deficit include perspective taking, abstract language, humor, and social problem-solving.

Advanced: Finally, for individuals whose deficits are not severe enough to become present at the previous stages, impairments may manifest as deficits in areas like social adaptability, theory of mind, monitoring/regulating the effect of their behavior on others, and knowing when/how to use supportive language with peers.

Evaluation and Differential Diagnosis

Standardized and validated evaluation instruments for the diagnostic assessment of SCD have yet to be introduced, and preliminary investigations suggest that the gold standard ASD diagnostic instruments (ADOS, ADI-R) in their current formats would not be reliable resources for identifying individuals with SCD (Foley-Nicpon et al. 2016). Standardized measures of pragmatic language may be useful tools for pre-evaluation screening or to supplement clinical evaluations and inform assessment decisions. Some measures likely to be utilized for these purposes include the Early Social Communication Scales for young children (8–30 months), the Children’s Communication Checklist-2 for older children and adolescents (4–16 years), and the Analysis of Language Impaired Children’s Conversation that can be used from 4 years old into adulthood (for a full review of available measures, see Adams 2015 and Norbury 2014). Such tools, however, should not be used in isolation to make diagnostic decisions. Instead, best practice recommendations suggest diagnostic assessment should be determined through evaluations by a multidisciplinary team of clinicians and include a thorough developmental history along with assessments of cognition and language to sufficiently assess areas of impairment and rule out alternative diagnoses.

Beyond the exclusionary diagnoses of intellectual disability, global developmental delay, or other mental disorders listed in the DSM-5, the primary disorders to consider for differential diagnosis with SCD are social anxiety disorder and ASD. Social anxiety disorder and SCD can be primarily differentiated based on onset of impairments, with SCD being present since early development and deficits associated with social anxiety disorder developing later in life. Meanwhile, ASD and SCD are differentially diagnosed based on the lifetime presence or absence of Domain B items (restricted interests and repetitive behaviors) from the ASD diagnostic criteria. Specifically, the DSM-5 states that a SCD diagnosis should only be considered if “the developmental history fails to reveal any evidence of restricted/repetitive patterns of behaviors, interests, or activities” (APA 2013, p. 49). This stipulation results in a diagnostic gap for individuals who have restricted interest and repetitive behaviors that are too limited to meet the Domain B criteria to obtain an ASD diagnosis but are exclusionary criteria from receiving a SCD diagnosis; and it has yet to be seen how this diagnostic gap will be addressed in practice.

Treatment

Some of the greatest implications of the diagnostic separation of SCD from ASD are with regard to therapeutic interventions. Specifically, over the past few decades the field of ASD has developed a well-established network of foundations and organizations engaged in outreach, education, research, benefits, support services, and public health. Meanwhile, a major area of concern is if the independence of these diagnoses will result in individuals with SCD being excluded from the valuable benefits of these networks (Brukner-Wertman et al. 2016). Further, since DSM-5 diagnostic criteria for SCD exclude the presence of restricted interests and repetitive behaviors, interventions made available to individuals with this diagnostic label may overlook subtle in these areas that can still exist impairments (e.g., difficulties with flexible thinking or change) and are potentially

additional sources of distress within this population (Christ et al. 2010).

Standard practices for treatment of SCD has yet to be determined; however, as communication difficulties are fundamental to the impairments of SCD, recommended intervention strategies will likely revolve around the incorporation of speech and language pathologists. To date, the only published randomized controlled trial of an intervention for SCD was conducted by researchers in the UK (Adams et al. 2012). Comparing the outcomes of children with pragmatic and social communication impairments (PLI) who received 16–20 sessions of direct, manualized intervention from a specialist speech and language pathologist to those who received treatment as usual, Adams and colleagues produced mixed findings. While blind and parent/teacher reports suggested significant improvements in some communication abilities, no improvements in structural language skills were noted based on standardized language assessments (Adams et al. 2012).

With the inclusion of SCD in the DSM-5 (and the anticipated inclusion of PLI in the ICD-11), the increased research and clinical focus on this set of social communicative impairments should result in increased understanding of areas of communicative strengths and deficits, as well as potential underlying weaknesses (e.g. theory of mind, executive functioning, central coherence) for this disorder, prompting the development of effective, disorder-specific intervention strategies. However, until such strategies are determined, it has been suggested that individuals with SCD should maintain access to the supports afforded to those with ASD, as the significant overlap in social communicative difficulties between these disorders would imply that interventions designed for those with ASD would likely benefit individuals with SCD as well (Brukner-Wertman et al. 2016).

Autism-Europe

Aurélie Baranger

Autism-Europe, Bruxelles, Belgium

Major Areas or Mission Statement

Autism-Europe (AE) is a European umbrella organization representing persons with autism and their families. AE was founded in 1983 and nowadays ensures liaison among more than 80 member associations of parents of persons with autism in 30 European countries, including 20 Member States of the European Union, governments, and European and international institutions. AE is also consulted by the World Health Organisation on matters relating to autism.

Its aim is to raise awareness across Europe of the fundamental rights and needs of people with ASD by representing them at EU level, and to promote positive actions and policies built on the social model of disability and aimed at the active inclusion of people with ASD, in line with the guiding principles of the UN Convention on the rights of persons with disabilities.

Its overarching statutory mission is to improve the life of all persons with autism by promoting their rights. AE members identified the following strategic objectives as their priorities:

1. Representing persons with ASD before all EU institutions.
2. Promoting the rights and dignity of persons with ASD.
3. Promoting awareness of the appropriate care, education, and well-being of persons with ASD.
4. Liaising with other non governmental organizations sharing similar objectives.
5. Promoting the exchange of accurate and evidence-based information about ASD, good practices and experience.

In order to implement its objectives and maximize its impact on EU policies, Autism-Europe has built strategic alliances with European social partners. AE currently holds the vice-Presidency of the European Disability Forum (EDF). It is also a founding member of the European Coalition for Community Living (ECCL) and the Platform of European Social NGOs.

Landmark Contributions

AE is widely recognized as a credible, representative organization across Europe and among parents, decision makers, social partners, the scientific community, and other stakeholders. This is demonstrated by the frequent ongoing contacts and requests for advice, intervention, partnership and collaboration in European and national projects, initiatives, and events.

In 1996, the *Charter of Rights for persons with Autism* was adopted as a written declaration by the European Parliament following its adoption by the Autism-Europe's Congress in Den Haag in 1992.

In March 2004, the Committee of Ministers of the Council of Europe made public the decision taken by the European Committee of Social Rights of November 4, 2003, whereby France was found to have failed to fulfill its educational obligations to persons with autism under the

European Social Charter. This decision upheld the collective complaint that Autism-Europe had lodged in 2003 against France. Autism-Europe's complaint was the first collective action to defend the rights of people with disabilities in Europe. Its importance in this respect was highlighted by the Council of Europe.

Also as a consequence, the Council of Europe published in 2007 the Resolution ResAP(2007)4 *on the education and social inclusion of children and young people with autism spectrum disorders* drafted with the cooperation of Autism-Europe.

Over the years, persons with ASD have been the target of false beliefs and they and their families have constantly suffered the consequences of unreliable treatments. Autism-Europe has made every effort to disseminate reliable, evidence-based information through collaboration with important professional organizations such as IACAPAP, ESCAP, and INSAR.

Autism-Europe's international congresses, organized every 3 years, provide an interdisciplinary forum to examine state-of-the-art scientific knowledge and current cultural approaches in the field of ASD. Autism-Europe ensures the high scientific quality of its international congresses through the support and participation of internationally renowned experts in the field of ASD.

During the VIII Autism-Europe International congress (Oslo, September 2, 2007), a *Position Paper on Care for Persons with Autistic Spectrum disorders* was presented and officially adopted by Autism-Europe, the International Association of Child and Adolescent Psychiatry and Allied Professions (IACAPAP), and the European Society for Child and Adolescent Psychiatry (ESCAP). It reflects the views of Autism-Europe, IACAPAP, and ESCAP on the approach to Autism Spectrum Disorders.

Autism-Europe also published in 2009 the document *Persons with Autistic Spectrum Disorders: Identification, Understanding, Intervention*, drafted by a team of European experts – Catherine Barthélémy, Joaquín Fuentes, Patricia Howlin, and Rutger van der Gaag. The document, which was drafted on a pro-bono basis by these experts, enables a better understanding of ASD and the needs of those affected by this condition. This

document is addressed not only to parents but also for all professionals who are involved in interventions for persons with ASD, and for European and national authorities responsible for the care of individuals with disabilities.

Major Activities

Representing Persons with Autism and Defending Their Interests at the European Level

Autism-Europe's engagement in defending the rights of persons with ASD, by means of legal instruments, such as the collective complaint against France lodged before the Council of Europe's Committee on Social Rights has been widely recognized by the European Institutions.

Autism-Europe is considered as one of the key EU networks in the field of disability and as such is regularly consulted in the process of policy-making to raise the concerns of persons with ASD and also benefit from the support of the European Commission to promote measures against discrimination.

Disseminating Evidence-Based Information About Autism as well as Promoting the Exchange of Knowledge and Best Practices on the Appropriate Care, Education, and Well-Being of Persons with ASD

Disseminating accurate and evidence-based information about autism is key in order to enhance understanding of autism within society and prevent abuse. The recognition of the specific needs of persons with Autistic Spectrum Disorders is essential to foster their inclusion in the community and improve their quality of life.

In order to promote self-advocacy, Autism-Europe has published a number of information documents and toolkits. Many documents of Autism-Europe are translated into easy-to-read format.

Autism-Europe's publications – which are available on its website – include:

- Information documents about Autistic Spectrum Disorders drafted in cooperation with experts.

- Position papers and reports addressed to European decision makers and public authorities.
- Toolkits for self-advocates, taking into account the latest legislative developments at EU level.
- Newsletters about the latest EU developments in the field of disability.
- LINK magazine to share information about important developments at EU and national levels.

Autism-Europe is also involved in a number of European projects – notably in the field of research, life-long learning and deinstitutionalization – in order to share its expertise and disseminate the results across Europe.

Every 3 years, Autism-Europe organizes an International Congress which aims at bringing together self-advocates, families, and professionals in order to share knowledge about state-of-the-art scientific findings in research and intervention.

The IX International Congress took place in Catania in October 2010, all the videos of the session are available on the Congress website and on Youtube. The congress was attended by over 1,200 delegates. Many of the most prominent researchers in the field of autism were present as speakers. AE has built a relationship of trust with both the scientific community and the professionals working in the field of ASD, which allows a fruitful cooperation in order to enhance the rights-based approach to care and intervention.

Promoting General Awareness of Autism

Every year, Autism-Europe also holds the European Days of Autism in October to share information at European level and raise awareness about ASD across Europe.

A wide range of activities are also organized by Autism-Europe and its members to mark the World Autism Awareness Day adopted by the United Nations.

Liaising with Other Non Governmental Organizations Sharing Similar Objectives

Finally, Autism-Europe cooperates closely with other European and international NGOs. It currently holds the vice-Presidency of the European

Disability Forum (EDF). AE strives for the recognition of the complex needs of persons with autism, and other kinds of disabilities requiring a high level of support. It is also a founding member of the World Autism Organization, the European Coalition for Community Living (ECCL), and the Platform of European Social NGOs.

University, New Haven, CT, USA

Synonyms

Childhood autism; Infantile autism; Kanner's autism

Short Description or Definition

As defined in DSM-IV Autistic disorder was the prototypical autism spectrum/pervasive developmental disorder. The condition, first described by Leo Kanner in 1943, is marked by severe and sustained problems in social development (autism) along with unusual communication and a range of problems typically subsumed under the term “resistance to change” – the last take the form of restricted or stereotyped patterns of behavior and interest as well as literal difficulties tolerating change. The

onset of the condition is in the first years of life. While many individuals with the condition eventually exhibit intellectual disabilities, these rates have decreased with earlier detection and intervention. The revision of the concept in DSM-5 (autism spectrum disorder) reflected a growing body of work suggesting that autism is indeed part of a broader range of conditions characterized by problems of various sorts including in social interaction; unfortunately this DSM-5 definition also excluded many individuals who previously had a diagnosis of autism or a related conditions (Smith et al. 2015).

In his first description of 11 cases, Kanner emphasized two essential features: (1) an inborn disturbance of affective contact, that is, with an apparently congenital “inability to relate” to people in usual ways, and (2) difficulties with change/insistence on sameness, including motor stereotypies, which Kanner viewed as an attempt by the child to maintain sameness. Although he did not emphasize communication problems as central to the definition of the condition, he did note a variety of unusual communication features including mutism (in many cases) and, for those with speech, pronoun reversal and echolalia. Although remaining profoundly influential, his original description also was misleading in some respects, for example, he did not appreciate the extent of cognitive (although often highly scattered) delays and his mention of high SES levels in parents suggested that the disorder was somehow more frequent in highly educated families. The latter contributed to an early mistaken impression that care-taking contributed to pathogenesis. His use of the term “autism” was based on Bleuler’s early use of the word to describe self-centered thinking in schizophrenia – this suggested a connection to childhood schizophrenia/psychosis that proved unwarranted. On the other hand, Kanner’s emphasis on developmental aspects of early social skills and his rich description were a landmark in the field.

Early research on the condition was complicated by confusion of the condition with childhood psychosis/schizophrenia and the emphasis on possible environmental/experiential factors in causation. Over time, the work of Kanner (1971) and Rutter (1972) helped clarify the lack of association with schizophrenia, and follow-up studies noted association with factors strongly suggestive of a familial, brain-based disorder (Folstein and

Rutter 1977; Volkmar and Nelson 1990). Rutter (1978) proposed a highly influential definition of autism based on the presence of social delay and deviance, communication problems, and unusual behaviors. His proposal had a major influence on the criteria for infantile autism when the condition was first recognized officially in DSM-III (APA 1980).

Categorization

Within DSM-IV autism was recognized as one example of the pervasive developmental disorders. The latter term was coined in 1980 for the overarching category of which autism was the prototype in DSM-III (APA 1980) and was synonymous with the more frequently used term “autism spectrum disorder.” Over time, the categorical definition of autism has evolved in some ways since Kanner’s first description. The D-10/DSM-IV definitions of childhood autism were essentially the same (ICD-10, which has both a clinical and research version, provides more potential for differentiation of atypical presentations of autism; see DSM-IV entry). In the current approach, associated medical conditions (if any) and other developmental and psychiatric problems (e.g., intellectual disability) are also coded in the multiaxial approach adopted by DSM-IV (Rutter et al. 1969). Although rates of association of autism with other medical conditions have been much debated, the strongest associations are with a limited number of genetic conditions such as Fragile X syndrome and tuberous sclerosis (Rutter et al. 1994). As noted above the DSM-5 definition is more stringent.

Epidemiology

Many epidemiological studies have been conducted with the DSM-IV/ICD-10 definitions. The median rate of autistic disorder (if strictly defined) is somewhere between 1 in 800 to 1,000 individuals (Hill et al. 2014). Although there is a widespread impression of increased rates of autism changes in diagnostic criteria, increased public awareness, better

diagnosis among more cognitively able individuals, and other factors likely account for much of this impression. Smaller and more thorough studies also report higher rates.

There is a noteworthy male predominance in autism (usually between three and five times as many cases in boys than in girls), but among lower IQ individuals the difference becomes less pronounced. Conversely among the most cognitively able persons, the difference is even more striking. Cultural and ethnic issues have been relatively uncommonly studied. Clearly, the early impression of a high-SES class predominance was unfounded (likely reflecting selective bias in initial referrals) (Grinker 2007). Within the United States, there is more concern about underdiagnosis in individuals coming from lower SES/poverty (Mandell et al. 2007). Cultural issues may impact treatment with considerable variations in entitlements and practice from country to country.

Natural History, Prognostic Factors, and Outcomes

The long-term outcome for children with autism appears to be improving (see Howlin et al. 2015). This does not appear to simply be a result of increased diagnosis among more able individuals. Rather earlier detection and intervention appear to have an important positive benefit for most children (National Research 2001). Over time, the number of individuals with autism who are capable of adult self-sufficiency and independence as adults has increased substantially. That being said, even with provision of good programs, not every child makes substantial improvement. Various issues, including factors apart from the child, can impact outcome, for example, in some countries, available services are limited, and even in more developed countries, factors like poverty may delay or impede case detection and service provision.

Diagnostic issues are most complex in young children (those under 3), although the increased body of work on infants and infant siblings of children with autism has contributed to greater awareness of the diagnostic challenges and need

for more robust methods of early detection (Chawarska et al. 2008). There is reasonable agreement that after age 3 years the diagnosis becomes relatively stable (prior to that time some, but not all diagnostic features, may be apparent). Often social-communication problems are more dramatic in younger children, but the required difficulties with change/stereotyped mannerisms may be the last to develop.

By school age, children with autism often develop more social interest but also may have more behavioral difficulties (Loveland and Tunali-Kotoski 2005). The latter can include agitation, motor mannerisms, and self-injurious behavior. As first noted by Kanner in adolescence, some children make gains while others lose ground (Kanner 1971; Shea and Mesibov 2005). More and more adults are able to be self-sufficient with many now attending college and post-secondary school programs (Volkmar and Wiesner 2009). Positive prognostic factors include higher levels of language and cognitive ability around age 5 years (prognosis can be difficult, however, and presumably depends on a range of factors) (Coplan 2000).

Clinical Expression and Pathophysiology

Marked changes over the course of development are common. A unifying theme, however, across development is the persistence of social difficulties. Although early speculation centered on the possible relevance of experience to pathogenesis, many different lines of research have strongly implicated neurobiological factors. This work includes the observation of markedly increased rates of epilepsy as well as various persistent neurological signs and symptoms (Minshew et al. 2005; Volkmar and Nelson 1990). Over the last decade, new approaches to neuromaging have also illustrated areas of possible difference associated with autism relative to factors such as perception of biological motion or relevance of faces (Schultz et al. 2000; Pinkham et al. 2008). A growing body of research has focused on social information processing in the brain – areas of interest include structures such as the amygdala (e.g., in social perception and social thinking),

frontal lobe regions and other areas involved in social information processing, and the fusiform face area.

Postmortem studies have revealed some abnormalities in specific brain regions as well as changes in overall architecture of the fine structure of the brain (Casanova 2007). Animal model work was originally limited to lesion studies (Bachevalier and Loveland 2006) but now includes genetic studies (e.g., based on knock out gene models) (Gupta and State 2007). The strong role of genetic factors has been suggested by various studies of siblings who are at substantially increased risk for autism. It appears that multiple genes are involved (O’Roak and State 2008). Several approaches have been used to identify potential contributing genetic mechanisms (Abrahams and Geschwind 2008).

Although the lay press has devoted considerable attention to the role of environmental factors (including immunizations) in autism, substantive data are lacking (Offit 2008; Wing and Potter, 2008).

Evaluation and Differential Diagnosis

Autism presents several major challenges for evaluation and diagnosis. Challenges include marked variability in skills, involvement of a range of service providers, and the potential for major change with intervention. Autism should be differentiated from other related disorders as well as other developmental disorders (e.g., of language or intellectual development) and from unusual profiles of development associates with sensory difficulties (e.g., deafness) or with severe neglect. Differences between autism and related disorders as defined in DSM-IV and ICD-10 relate both to historical information and current clinical presentation (key features are summarized in Table 1).

Assessment is complicated by the often strikingly varied cognitive profiles. In autism, nonverbal skills are typically more preserved than verbal ones. In language disorders, social interest and motivation remain even in the face of sometimes severe communication problems. In mental retardation without autism, social skills are usually not dramatically different from other cognitive abilities and may be

Autistic Disorder, Table 1 Differential diagnostic features of autism and nonautistic pervasive developmental disorders

Feature	Autistic disorder	Asperger's disorder	Rett's disorder	Childhood disintegrative disorder	Pervasive developmental disorder NOS
Age at recognition (months)	0–36	Usually >36	5–30	>24	Variable
Sex ratio	M > F	M > F	F (?M)	M > F	M > F
Loss of skills	Variable	Usually not	Marked	Marked	Usually not
Social skills	Very poor	Poor	Varies with age	Very poor	Variable
Communication skills	Usually poor	Fair	Very poor	Very poor	Fair to good
Circumscribed interests	Variable (mechanical)	Marked (facts)	NA	NA	Variable
Family history – similar problems	Sometimes	Frequent	Not usually	No	Sometimes
Seizure disorder	Common	Uncommon	Frequent	Common	Uncommon
Head growth decelerates	No	No	Yes	No	No
IQ range	Severe MR to normal	Mild MR to normal	Severe MR	Severe MR	Severe MR to normal
Outcome	Poor to good	Fair to good	Very poor	Very poor	Fair to good

M male, *F* female, *MR* mental retardation, *NA* not applicable

an area of strength. A common source of confusion is the frequent presence of stereotyped mannerisms in association with severe intellectual impairment. As a practical matter, stereotyped mannerisms are not particularly diagnostic of themselves and have significance for autism only when associated with social-communication deficits.

Children, adolescents, and adults with autism typically have problems in various areas (cognition, adaptive functioning, communication, social skills, and behavioral difficulties). Many different tests have been developed for purposes of screening (Coonrod and Stone 2005) and diagnosis (Lord and Corsello 2005). Children with autism present many challenges for assessment, and considerable skills may be needed (Volkmar and Wiesner 2009). Provision of a comprehensive, integrated view of the individual (attending to both strengths and weaknesses) with provision of an intervention program should be the goal of assessment (Volkmar and Wiesner 2009).

Treatment

A substantial body of work supports the use of behavioral and educational interventions in autism (Volkmar and Wiesner 2009). Increasingly much of this work is strongly evidence based (Reichow and Wolery 2009). The most effective programs rely on behavior modification and special education with a goal of minimizing negative effects of autism on learning and maximizing more normative developmental processes. Drug treatments can be helpful in some instances (particularly for agitation and behavioral difficulties) but do not seem to address core social dysfunction (at least to date). Agents like the second-generation neuroleptic risperidone have been shown, in double-blind studies, to be more effective than placebo (McCracken et al. 2002).

Alternative and complementary treatments are common but lack substantive efficacy data. Parents should be helped to understand the

importance of pursuing proven treatments (Volkmar and Wiesner 2009). Except in selected cases, traditional psychotherapy is not usually helpful, and even in these cases, it often takes on a much more explicit, “life coaching,” model.

individuals with outstanding talents. Subsequent research has suggested that these skills are most commonly seen in the domains of art, music, and numerical calculation. A change in terminology from “idiot savant” to “savant syndrome” was later proposed by Treffert (1989) who also outlined a hierarchical system for categorizing levels of talent proficiency. In addition to avoiding the negative connotations of the earlier term, Treffert’s new term reflected an increased awareness that intellectual disability was not a necessary feature of the savant syndrome.

Although savant skills have been described in individuals with Tourette’s syndrome, frontotemporal dementia, manic depression, language impairment, and congenital blindness, the savant syndrome is most strongly associated with autism spectrum disorders. The early prevalence rate for savant skills, based on parental report, was 9.8%, a figure that was ten times greater than in intellectually handicapped populations (see Heaton and Wallace 2004, for details). However, more recent investigations of splinter and savant skills (Howlin et al. 2009; Bennett and Heaton 2012) observed greatly increased prevalence rates and suggested that up to a third of individuals with ASD may possess unusual talents.

Prominent theoretical accounts of autism have implicated atypical cognitive processing and enhanced perceptual discrimination in the emergence of talents (see Mottron et al. 2009). However, the results from several studies have reported superior working memory (Bölte and Poustka 2004; Bennett and Heaton 2017) and obsessional traits (Bennett and Heaton 2017) in individuals with savant talents, and current theoretical models do not account for these findings

There are several major challenges facing researchers working in this area. First are difficulties in determining exactly how the definitions of Treffert’s (1989) three-tier categories should be operationalized. Quantifying skill levels in domains like art and music, where standardized assessments are not available, introduces a degree of subjectivity that could compromise cross-group comparisons. Some savant skills, for example, calendar calculating, are rare in typical

London, UK

Definition

In 1866, Edouard Seguin coined the term “idiot savant” to describe intellectually handicapped

populations, and questions about appropriate comparison groups must be carefully addressed. There is a final fundamental question that results from the definitional shift from “idiot savant” to savant syndrome. There is currently no consensus about whether intellectually able, talented individuals with autism should be accorded savant status (see Heaton and Wallace 2004; Miller 1998). The rise in the numbers of intellectually able individuals diagnosed with ASD and the observed increase in the prevalence of special talents in these groups (Howlin et al. 2009; Bennett and Heaton 2012) bring the importance of resolving this question into focus. The study of savant syndrome has implications for both theory and practice, and the development of new definitions and methodologies will be an important future goal for psychologists working in this area.

Definition

Autistic traits are normally distributed, heritable, are stable cross-culturally, and are also apparent in relatives of autistic people. Traits associated with the autism spectrum can be measured with tools such as the Autism-Spectrum Quotient (Baron-Cohen et al. 2001) and allow for designs that take advantage of the variability of autistic traits across individuals with or without a diagnosis. Autistic traits measured in this way correlate with behaviors and performance on tests in non-autistic samples similar to performance in autistic samples (Almeida et al. 2010; Stewart and Ota 2008; Stewart et al. 2009).

In the context of autism research, auditory discrimination has been studied primarily on the dimension of pitch (or rather its acoustic correlate, fundamental frequency), and also of intensity and duration.

Historical Background

Autistic people tend to outperform their non-autistic counterparts on perceptual tasks where there is a benefit in being able to process the local detail over the “gestalt.” Mottron and colleagues suggest that autistic people have Enhanced Perceptual Functioning in which there is an enhanced ability to process detailed perceptual information (see entry ► [Enhanced Perceptual Functioning](#)). Happe and colleagues (see ► [“Weak Central Coherence”](#) entry), in comparison, suggest that autistic people show Weak Central Coherence in which the ability to focus on the “local” detail is preserved or enhanced but there is a weakening of the ability to integrate information into a meaningful whole or a “gestalt.”

Autistic children and adults show enhanced performance in a range of tasks which depend on a detailed, accurate representation of the stimuli. Within the visual domain, autistic individuals show reduced interference from the whole picture when completing whole versus segmented patterns in an adapted block design task (Shah and Frith 1993). Similarly, enhanced performance has been found on the embedded figures task, in which participants are required to find a design which is hidden in a larger picture. Tasks such as these require the participant to ignore the “gestalt” of the whole and focus on the local detail in complex designs. This enhanced performance is also shown in those with high levels of autistic traits but who do not have a diagnosis of autism. In a similarly adapted block design in which there were whole/unsegmented designs and segmented designs, Stewart et al. (2009) found superior performance in the whole/unsegmented designs in those who scored high on autistic character traits versus those who scored low, whereas the groups performed equivalently on the segmented designs. This pattern of performance was also found for a radial search task, where those with high autistic trait scores outperformed those who low autistic trait scores (Almeida et al. 2010).

A similar effect has also been found within the auditory domain. One such demonstration involves the so-called Ganong effect, which reflects the extent to which phonetic categorization shifts to make the percept a known word. For example,

when adults listen to voice onset time (VOT) continua between a real word and a non-word, such as *gift-kift* and *kiss-giss*, their judgment of the mid-point stimuli tend to shift toward the real-word end (i.e., *gift* and *kiss*) even when the onset consonants in the stimuli are acoustically identical. However, those who scored higher on AQ were less influenced by the lexical (“global”) information and were more likely to respond in terms of the actual acoustic (“local”) difference in both adults (Stewart and Ota 2008) and children (Ota et al. 2015). Furthermore, Stewart and colleagues found that auditory discrimination of speech stimuli along the same dimension (i.e., VOT difference) was less categorical in autistic adults than in neurotypicals (Stewart et al. 2018). In other words, while neurotypicals were more sensitive to acoustic differences between categories (i.e., /g/ vs. /k/) than those within categories, autistic individuals showed a more invariant level of sensitivity to acoustic differences. In their literature review, Haesen and colleagues (Haesen et al. 2011) report a range of other evidence consistent with the idea that autistic individuals’ auditory processing is locally oriented and less susceptible to global interference and propose that this pattern of auditory performance in autism can be explained by atypical brain lateralization.

There is also a body of evidence in the auditory domain according to which autistic individuals have an enhanced ability to discriminate perceptual stimuli which is in line with the model of Enhanced Perceptual Functioning (see ► [“Enhanced Perceptual Functioning”](#) entry). Documented most reliably is the observation that autistic individuals exhibit better discrimination of differences in pitch compared to non-autistic individuals. For instance, Bonnel et al. (2010) found enhanced ability in autistic children and young adults to categorize pure tones on the basis of their pitch, but not on the basis of intensity. O’Riordan and Passetti (2006) used an adaptive paradigm in which, across trials, a target tone gradually became closer to a reference tone in fundamental frequency. They found that autistic children tended to shift from a “different” to “same” response later than non-autistic children, which can be interpreted as evidence for higher pitch sensitivity in autistic children. Jones et al.

(2009) assessed individual thresholds on frequency, intensity, and duration in an autistic adolescent sample and controls. While no differences were found at the group level, a subset of the autistic adolescents, who were identified as having delayed language onset and average intellectual ability, showed an enhanced ability to discriminate stimulus differences in fundamental frequency. This effect did not extend to intensity or duration. However, not all studies have found autistic individuals to have better auditory perceptual ability. In fact, Kargas et al. (2015) report deficits, rather than enhancement, in auditory discrimination of frequency, intensity, and duration in autistic adults as compared to age-matched controls.

Current Knowledge

Further evidence for an enhanced perceptual processing in autistic people as well as in those who score high on autistic traits has been found both in the visual and auditory domains. Questions arise, therefore, as to whether there is a common perceptual mechanism across modalities or features, and whether autism or autistic traits explain the differences in perceptual processing, or whether there is another factor associated with this enhancement, and what the mechanism behind such an enhancement would be.

Stewart et al. (2018) asked whether there was a correlational pattern of enhanced discrimination across pitch, time, and intensity in non-autistic participants who scored on autistic character traits. Participants were asked to discriminate between two tones for the pitch and intensity tasks and between two pairs of tones in the time-interval task. Each trial consisted of one reference and one target stimulus, and the position of the target stimulus was randomized across with equal probability across trials. Similar to other studies (Bonnell et al. 2010; Jones et al. 2009), the references were fixed for the pitch task. However, both a fixed and a variable reference task were used for time interval. Stewart and colleagues found that the pattern of enhancement did occur in those who scored high on autistic traits and that autistic trait scores correlated with both pitch discrimination

and time-interval discrimination in the fixed reference tasks. However, they did not find any relationship between autistic traits and discrimination of intensity or time interval in the variable reference task. They suggest that the correlations show an ability to form stable perceptual representations of auditory events in the time and pitch dimensions. Furthermore, they suggest that such stable perceptual representations may be formed because both pitch and time interval can be coded in an absolute fashion, whereas intensity cannot. The findings are in line with the Enhanced Perceptual Functioning model (see ► [“Enhanced Perceptual Functioning”](#) entry), which suggests that autistic people have enhanced low-level processing of basic perceptual information. However, a caveat to this explanation for enhanced discrimination ability is that there could be confounding factors.

On potential factor may be the design of tasks and differing task demands (see, e.g., Barry et al. 2013). Banai and Ahissar (2006) suggest that variation in performance, due to differing task demands, may be due to the ability to form an accurate representation of the auditory stimulus. This ability to form a stable representation of an auditory stimulus is something which is thought to be impaired in dyslexic participants (Banai and Ahissar 2006) but enhanced in those who score high on autistic traits (Stewart et al. 2018).

It may also be important to take into account language and literacy abilities in the design of the study. Pitch (frequency) discrimination deficits are associated with language and literacy impairments, although there may be no causal relationship rather discrimination differences may be a risk factor for differences in reading and literacy (e.g., McArthur and Bishop 2004). To note, is that Jones et al. (2009) showed the converse in autistic people, in that those with delayed language onset had an enhanced ability to discriminate frequency.

Effects could be due to differences in IQ, as evidence shows that perceptual ability, for instance, pitch discrimination, is strongly related to nonverbal or performance IQ ($r = 0.92$; Deary et al. 2004). There are a number of paradigms where IQ is related to discrimination. For instance, those who score high on a measure of non-verbal IQ (Raven's Progressive Matrices)

show shorter response times and higher accuracy on an oddball-type task of auditory discrimination using tones that differed in frequency (De Pascalis et al. 2008). In this study, participants heard a series of tones, 85% of which were the baseline tone and 15% were the target tone with a higher frequency. The participants' task was to indicate when they heard the target tone. In addition, Kuppen and colleagues (Kuppen et al. 2011) found that children with low IQ and who were poor readers had higher thresholds for frequency discrimination (i.e., they were worse at discriminating) than chronologically age-matched controls. Studies in autistic people and on autistic traits assessing perceptual discrimination tend to match on IQ by group but not individually. In studies, where the groups have been matched on IQ, IQ did not have a significant relationship with discrimination for pitch, time, or intensity, nor with autistic traits (e.g., Stewart et al. 2018). However, it may be important to match individually on IQ and on other factors such as reading ability.

It is important to note that IQ tests may be performed differently by autistic people and those who score on autistic character traits. For instance, Dawson found large differences between performance on the Wechsler scales of intelligence versus the Raven's Progressive Matrices in autistic people but not in non-autistic people, suggesting that in some cases, IQ may be underestimated (or potentially overestimated) in autistic people due to the measure used. Even within the Raven's Progressive Matrices, researchers have found that those who score high on autistic traits performed better performance on visuospatial items than on verbal-analytic. Given that IQ is known to relate to perceptual performance, it is of key importance to adequately control for IQ in these studies.

Meilleur et al. (2014) assessed performance in autistic and non-autistic adults across two visual and two auditory tasks, using both the Wechsler Intelligence Scale and the Raven's Progressive Matrices as IQ measures. The visual tasks were a modified block design task and a luminance contrast discrimination, and the auditory tasks were pitch and melody discrimination. The autistic participants showed enhanced pitch discrimination

even when controlling for IQ (both measures). But differences in the performance on the block design disappeared when IQ was controlled for. There were no group differences in the low-level visual task or in the melody discrimination. The authors recommend that a wide range of tasks are used in order to test whether there is an underlying common perceptual factor which may drive performance on perceptual tasks in autistic people but not in non-autistic controls. The tasks chosen were limited to four, and these may not be the most sensitive tasks. In addition, the melody discrimination task may not require "global" processing as the pitch contours that are used consist only of simple ascending and descending pitch directions which may be regarded as a "local" feature.

Future Directions

There is a substantial body of work that assessed perceptual and specifically auditory processing across the autism spectrum, which has helped identify where and why there may be particular enhancements. It is of interest to identify which aspects of behavior also occur in those without a diagnosis of autism but who score highly on autistic character traits. This is important as we know that aspects of autistic traits can be predictive of a range of behaviors. Future research must take into account a range of designs and use a range of stimuli to help identify potential mechanisms behind these identified differences. Techniques such as brain imaging may also be able to shed some light on the underlying mechanisms. In addition, the samples must be well controlled and information regarding IQ, reading, and literacy taken into account. It is of societal interest to assess how far these differences in processing may be related to aspects of functioning, health, and well-being.

Autistic Traits in Prison Populations

Diana Rafaela
Centro Hospitalar do Baixo Vouga, Aveiro,
Portugal

Definition

The link between ASD and criminality, including extremely violent offenses as serial killing or mass murdering (Allely et al. 2014), but also

concerning cybercrime (Seigfried-Spellar et al. 2015) has gained widespread public notoriety. Nevertheless, the available evidence does not favor the hypothesis that autistic individuals are more likely to engage in unlawful behavior than the general population and may in fact be less so. Yet, the current literature points to an overrepresentation of people with ASD or autistic traits in the criminal justice system (CJS), even though they are apparently not more likely to commit illegal acts. Besides the implications this has in terms of service provision to this population, whose needs seem to be poorly met in several instances across the legal system, it also highlights the importance of determining which factors increase the risk for autistic individuals to be incarcerated, in order to optimize care and target interventions to prevent this dreadful outcome for autistic people.

Historical Background

Although the field of intellectual disability (ID) in the CJS has a long tradition, with numerous studies on the prevalence of ID in different forensic settings and its implications, the focus in other neurodevelopmental disorders has only recently gained attention from the scientific community, and more so for attention deficit hyperactivity disorder (ADHD), for which a large meta-analysis of prevalence is already available, than for ASD (Young et al. 2015). This is hypothesized to be a consequence of the late recognition of these disorders in adulthood, which were mainly dealt within child services and not officially recognized by the DSM until the 1980s (King and Murphy 2014). Moreover, it is likely that the higher prevalence and the more externalizing symptoms and psychiatric comorbidities of ADHD have led to a greater investment in this area, and not ASD.

However, the association between violent behavior and ASD, independently of ID, was already mentioned by Hans Asperger in 1944 in one of his case descriptions (Im 2016), and nonviolent, but unlawful behavior was also described by Lorna Wing in her 1981 paper on Asperger's (Woodbury-Smith and Dein 2014).

The generalized interest in the relationship between autistic traits and criminality also began to rise in association with extremely violent offenses, committed by (allegedly) autistic individuals, which received extensive media coverage (Allely et al. 2014). Despite the posthumous, not rigorous nature of most diagnosis, the possibility that autistic characteristics could render people on the spectrum liable to violent criminality interested the scientific community, and studies on the subject began to emerge.

Besides analyzing individual cases of offenders and studying criminal behavior in autistic cohorts, some authors have taken a different approach to this subject, beginning in the 1990s, namely, obtaining the prevalence of ASD or autistic traits among prisoners, which has led to the recognition that there is a higher than expected number of autistic individuals in the CJS and has opened a field of interest of its own, expected to affect policy-making and service provision throughout the legal system and specifically in custodial settings (Robertson and McGillivray 2015).

Current Knowledge

Prevalence

Since it emerged, the scientific interest in the subject has grown in the past few years.

The literature in general points to an overrepresentation of individuals with ASD in the CJS, with estimated prevalences ranging from 2% to 27% in a systematic review that included seven studies (King and Murphy 2014). Figures were higher for samples obtained in psychiatric hospitals than in the general prison system, but this is in excess of the expected population prevalence of around 1%, even for the lower end of the interval. Nonetheless, several methodological pitfalls prevent the drawing of rigorous conclusions, as most of the studies employed biased samples (e.g., those referred for forensic psychiatric evaluation only) and substantial heterogeneity existed across studies regarding the terminology and the diagnostic procedures. Also of note, most of the samples were exclusively male, with fewer than 200 women included.

Most prevalence studies use a categorical approach to autism (i.e., either presence or absence of an ASD diagnosis), but there is evidence that individuals without an ASD diagnosis but with a high load of autistic traits are also overrepresented in the CJS, although less publications have addressed this issue. Two studies used the Autism Spectrum Quotient (AQ) to measure autistic traits among prison inmates albeit without a control group. Fazio et al. (2012), in their prevalence study with a sample of 431 male inmates, obtained a mean score of 20; Robinson et al. (2012), in a study with 126 prisoners of varying ages and both genders, reported an average score of 20,1. This contrasts with the reported mean AQ scores of around 18 in the general male adult population. A third study (Loureiro et al. 2018) that measured the AQ in a prison sample of 101 male inmates and included a control group found significant differences regarding autistic traits between the groups (mean AQ of 20,6 in the prisoners and 18,1 in the controls; $OR = 1,13$, $p = 0.002$) after controlling for potential confounders – age, education, psychopathology, psychopathy, and ADHD.

Core Autistic Traits and Imprisonment

Taken together, these studies suggest that autistic individuals (either given an ASD diagnosis or not) are overrepresented in forensic settings. Several reasons are invoked to explain these findings, namely, the characteristics of autistic people themselves, which may confer a higher risk of engaging in illegal activity and/or being sentenced to prison (Haskins and Silva 2006; Lerner et al. 2012; Im 2016).

Individuals with an ASD may be at increased risk for criminality due to the failure to understand social rules and hierarchies and the inadequacy and/or the consequences of some behaviors. They typically have difficulties in evaluating the emotions, thoughts, and intentions of others, leading to misunderstandings in reciprocal relationships. Emotional regulation is commonly impaired, and people on the autism spectrum can be extremely obsessive in the pursuit of their special interests, disregarding dangers and (legal) obstacles in the way. Also, their naivety, paired with an eagerness

to comply and avoid confrontation, renders these individuals susceptible to exploitation by others: they are easy to manipulate into (unintentionally and unknowingly) committing illegal acts.

The same holds true for autistic individuals without an ASD diagnosis, due to the aforementioned cognitive and affective styles, without the social reclusion imposed by more severe phenotypes, not to mention that aggression and other problem behavior are seldom criminalized for individuals with higher degrees of incapacity but are unlikely to be tolerated when no obvious disability is found (Michna and Trestman 2016).

While some studies point to a higher likelihood of criminal behavior among people with an ASD, the majority reject this hypothesis (King and Murphy 2014) and, in fact, find evidence of lower rates of criminality in this population. Only one population-based study tried to address this issue, with a cohort of almost 3.000.000 subjects aged 15–27 years (5739 diagnosed with an ASD). It reported and unadjusted relative risk (RR) of criminality, for ASD individuals without an ID, of 1,39. However, this association did not remain after adjusting for ADHD or conduct disorder (Heeramun et al. 2017). In fact, the tendency to rigidly follow explicit rules has been pointed as an autistic feature that promotes law-abiding behavior (Im 2016).

Moreover, no confirmation was found for the hypothesized link between autistic traits and particularly violent crimes, such as murder or rape, although the available evidence does seem to find an increased risk for arson (King and Murphy 2014) and personal offenses in general and a diminished likelihood of property crimes. The possibility of the highly mediatized link between autism and cybercrime is also at the moment still under debate (although a weak correlation between autistic traits and deviant computer behavior is found in the very few studies available on the subject – Seigfried-Spellar et al. 2015).

So, other hypotheses have been raised regarding the reasons for the overrepresentation of autistic individuals in the CJS, without an obvious tendency among ASD individuals to commit crimes.

One other possibility is that the main characteristics of the core autistic phenotype may

prevent individuals on the spectrum from avoiding incarceration. It has been suggested that features such as the lack of appropriate social support networks, poor communication skills, rigidity, literality, and catastrophic reactions to anxiety not only make it more unlikely for the autistic offender to avoid detection but also have a negative impact on the detention process and especially the trial itself, where the autistic person is often perceived as remorseless and uncaring or giving false accounts (Woodbury-Smith and Dein 2014; Robertson and McGillivray 2015; Michna and Trestman 2016). In that scenario, ASD individuals would have greater rates of incarceration than their counterparts, in the exact same legal contexts.

Although autistic traits can potentially have a negative impact in all the steps that can lead to incarceration, some seem to be especially

detrimental in specific stages of the process. Table 1 attempts to summarize the available literature on how core autistic features are thought to affect unlawful behavior, the sentencing process, and the amount of time spent in prison.

Other Risk Factors

On the other hand, some authors argue that the higher prevalence of illegal behavior in autistic people is more related to psychiatric comorbidities such as psychosis, personality and affective disorders or substance abuse, and not to autistic traits themselves (Im 2016; Heeramun et al. 2017). In general, offenders with ASD are less likely to have coexisting drug or alcohol misuse than the general prison population, but the presence of other mental health issues is a contributing factor for criminality in ASD, as it is for the neurotypical population.

Autistic Traits in Prison Populations, Table 1 Putative factors contributing to the higher than expected prevalence of autistic people in prisons

Factors that affect imprisonment and sentence length	Negative implications of autistic traits
Liability to commit criminal offenses (either by own moto or influenced by others)	Aggressive outbursts directed to others due to poor emotional regulation, intolerance to the unexpected, sensory issues Obsessional pursuit of interests Difficulty interpreting other's intentions and emotions and forming appropriate relationships Difficulty anticipating and appreciating consequences of one's own behavior Utilization as "stooges" (psychopathic individuals prey upon naïve and acquiescent individuals to perform their risky criminal activities)
Increased probability of more severe penalties than neurotypical peers (in the same legal context)	Reaction to arrest (aggression, freezing while others escape, etc.) Tendency to immediately confess, even to additional crimes not under trial Difficulty interacting with different players throughout the CJS Over acquiescence and suggestibility during interviews Facial expression and prosody come across as arrogance and lack of remorse Idiosyncratic use of language, literality, use of words without complete understanding of meaning and poor appraisal of timelines of events may give rise to false testimony
Extended sentences due to inside prison behavior	Victimization by fellow inmates results either in isolation placement for protection (and further failure to socialize) or heteroaggressivity (including displaced toward authority figures), preventing earlier release on "good behavior" terms Failure to engage in and/or successfully complete rehabilitation programs that are usually group-based and poorly fitted for autistic individuals Increased risk of institutionalization

It has also been suggested that the association between criminality and autism may only occur for some individuals on the spectrum who display callous-unemotional traits and are phenotypically closer to psychopaths (Rogers et al. 2006).

Indeed, much debate has been raised about this issue since the original description of Asperger's "Autistic Psychopathy." Although the term psychopathy was, at that time, employed as a synonym of personality disorder, some authors have argued that it may well have "more explanatory power" than previously perceived (Fitzgerald 2001), and the debate around this subject has given rise to a substantial body of knowledge.

Psychopathy is most commonly regarded as a construct that encompasses such features as dominance-seeking, cruelty, manipulation, predatory violence, impulsive, reckless behavior, lack of emotional reactivity, and affective indifference and is primarily associated with poor empathy processing. Empathy is defined as the capacity to feel or imagine another person's emotional experience, and an atypical empathy development results in antisocial behavior. Autism and psychopathy are viewed as two prototypical "disorders of empathy" (Bird and Viding 2014).

So far, the favored hypothesis seems to be that of a divergent profile between psychopaths and autistic people, with the first lacking emotional empathy (the vicarious experiencing of another person's emotions) and the latter lacking cognitive empathy (the capacity of understanding other people's perspectives or theory of mind).

However, regardless of the shared risk factors with the population at large, it should be noted that, in the few studies that looked specifically for the motive why autistic people committed the offenses, they all seemed to be related to the autistic traits themselves, although some sort of acute stressor was usually also found (Haskins and Silva 2006; Helverschou et al. 2015; Im 2016). Moreover, Loureiro et al. (2018) found autistic traits to be independent predictors of incarceration, when taking into account variables as general levels of psychopathology, ADHD, and psychopathy.

In conclusion, autistic characteristics can act as independent risk factors for being sentenced to prison, besides those shared with the population

in general – not only psychiatric comorbidities and psychopathy but also low socioeconomic status, low IQ, and a history of adversity in childhood (Helverschou et al. 2015). This needs to translate into differentiated service provision for this population, who must benefit from tailored interventions that address autism-specific criminogenic needs along with those risk factors shared with the non-autistic offender population.

Service Provision for Autistic People in Prisons

Concerns have been raised about the adequacy of prison or even general psychiatric high-security facilities to accommodate the needs of this particular population during the sentence. There is even less information concerning this subject, although a few studies have begun to shed some light on the experiences of autistic people during the process of arrest, investigation, trial, and imprisonment (Helverschou et al. 2015).

While the personal experiences of people with ASD are primarily negative for the entire process, they are less consistently so when it comes to the imprisonment itself. In fact, the social isolation inherent to life in prison may be perceived as less stressful to autistic individuals than it is for the general population, and some aspects of prison life are regarded as positive, namely, the structured environment, with predictable routines and organized activities that allow for less free time. Not all establishments offer this type of structure, though, and some individuals fare worse under less supervised environments, especially if housed with unselected prisoners, when predation and bullying by fellow inmates is a concern. The ability to avoid conflict in overcrowded facilities with truculent, antisocial individuals is dependent on a highly developed social cognition to interpret and act accordingly to the hierarchies of power and control that ASD people distinctly lack. Indeed, autistic prisoners seem to be at a greater risk of victimization while in prison and to spend more time in solitary confinement for their own protection, although data is particularly scarce and only a few individual cases have been published (Helverschou et al. 2015). It has also been hypothesized that people on the spectrum may be more susceptible to institutionalization (the loss of personal sense of responsibility for one's own acts and dependency

upon others to attend to daily living tasks) and thus have increased difficulties adjusting to life after prison (Robertson and McGillivray 2015).

In the past few years, efforts have been made to accommodate people with ASD throughout the CJS, although these are mainly localized to more affluent countries. For instance, the UK National Autistic Society keeps a comprehensive and updated “Criminal Justice” section with information for professionals who may come into contact with autistic individuals in the different settings along the CJS (<https://www.autism.org.uk/professionals/others/criminal-justice.aspx>) and provides autism accreditation specifically for prisons. The placement of autistic individuals under structured and well-supervised environments, paired with other prisoners that share the same traits and are perceived as more stable and less invasive by the staff, seems to increase the level of adjustment to prison life (Helterschou et al. 2017).

A related problem is the issue of underdetection of autism in prisons. Even if a facility has the capacity to put in place differentiated strategies to accommodate for autistic individuals, they still have to be identified first. In some of the prevalence studies conducted so far, autism was only diagnosed during the study interviews, which implies a low rate of detection through that point (Heeramun et al. 2017; Helterschou et al. 2015). There is a distinct possibility that the majority of autistic individuals, especially those on the less severe end of the spectrum, remain undiagnosed throughout the time that they remain in prison, even more so in less developed countries, where autism awareness levels are much lower and healthcare, social, and legal system’s budgets are tight.

Future Directions

There is now a growing interest in the field of ASD and autistic traits in the CJS and particularly in prison settings that is hoped to aid in the development of better services for the needs of those autistic individuals that come to experience imprisonment. Nevertheless, there is still a wide gap to overcome in many domains, as Woodbury-Smith and Dein (2014) and King and Murphy (2014) have summarized in their reviews. As

estimates of offending in the autistic population are fortunately low and the available estimates of ASD prevalence in custodial settings are not too high either, collaborative efforts among investigation centers across different countries are necessary to draw robust conclusions.

Figures for the prevalence of ASD in prisons require clarification. The available studies have methodological flaws that preclude the drawing of safe conclusions and employ differing diagnostic methodologies that mostly lack developmental corroboration from relatives. It would be beneficial to study unbiased samples with robust and standardized tools that would allow to pool results from different countries to better estimate the true prevalence of autism in prisons, as this is a *sine qua non* condition for budget allocation to specialist services in this area. Woodbury-Smith and Dein (2014) also raise the important question of the almost complete lack of data regarding the female population, which parallels the lag in this regard for the entire ASD population.

Moreover, specific recommendations on diagnostic procedures for those individuals who remain undiagnosed up to their imprisonment would be an important step toward the better care for autistic people while in prison. Neurodevelopmental disorders should be an integral part of standardized interviews that guide the initial health assessment when a person first enters the prison system, as exemplified by the Comprehensive Health Assessment Tool – CHAT (The Offender Health Research Network 2013).

Another important issue that demands a more thorough approach is the systematization of which specific autistic traits and environmental triggers are more likely to contribute or prevent criminal behavior and in what way. Only through extensive data collecting from interviews of convicted autistic offenders and their close contacts could a definite pattern of motives begin to emerge. This would enable the development of specific, individualized interventions to address these issues in a timely fashion, should they emerge, and prevent the offending behavior when possible, either through environmental modifications, therapy, or psychotropic medication.

For those already serving a prison sentence, there is a need to adapt existing programs or

develop other therapeutic interventions aimed at preventing reoffending, as the existing traditional cognitive and group-based alternatives may not be suitable for autistic individuals. Moreover, a more general habilitative approach, including social cognition training, may be necessary to achieve the best results (Woodbury-Smith and Dein 2014). On the whole, it seems that the general risk-need-responsivity method to evaluate and manage risk in offender populations (Bonta and Andrews 2007) can be applied to autistic individuals, as it is already grounded on individual criminogenic needs and static and dynamic risk factors.

Lastly, the interventions would then have to prove their usefulness against objective outcome measures, as living arrangements, employment, relationships, and recidivism. As cost is higher for more specialized services, there is also a need to compare outcomes among different pathways of care (autism accreditation or specialist consultations in prisons or general forensic psychiatric facilities versus specialized autism custodial settings).

Autobiographical Writings

Laura Crane
 Centre for Research in Autism and Education
 (CRAE), UCL Institute of Education, University
 College London, London, UK
 Department of Psychology, Goldsmiths,
 University of London, New Cross, London, UK

Definition

Autobiographical writings refer to personal narratives about the self. The autobiographical writings of individuals with autism include life stories, memoirs, letters to correspondents, online blogs and articles, entries in online chat rooms, and accounts of experiences (as told to researchers or clinicians). Notable autobiographical writings in the autism field include those of Temple Grandin, Donna Williams, David Miedzianik, Lianne Holliday Willey, Therese Jolliffe, Wendy Lawson, Daniel Tammet, and Tito Mukhopadhyay. While

some autobiographical writings of individuals with autism were originally intended for publication, others were initially private correspondence that has been made public at a later date. Many autobiographical writings are solely the work of an individual with autism, while others have been edited or cowritten, usually by an individual without autism. Although some autobiographical works explicitly outline the degree of editing and/or cowriting by individuals without autism, this is not always the case. Autobiographical writings have been used as a tool through which one can gain an “inside” view of living with an autism spectrum disorder. Individuals with autism have also used their autobiographical writings for purposes of advocacy, using their personal experiences to enable people to have a better understanding of autism.

Historical Background

Early clinical accounts of autism (e.g., Asperger 1944/1991; Kanner 1943) provided an insight into the world of autism from an observer perspective, making inferences about the individual on the basis of parental report, neuropsychological evaluation, and clinical assessment of behaviors. This was followed by a long tradition of research on individuals with autism that provided further insight into the nature of the condition, often on individuals with low intellectual abilities who may not be able to verbally express their experiences (e.g., Hermelin and O'Connor 1970). It was not until much later that (often, but not exclusively, high-functioning) individuals provided their own personal reports of living with autism. Complementing the earlier clinical accounts and experimental investigations, these autobiographical writings enabled a greater understanding of the experience of living with autism.

Current Knowledge

Theories of autism would predict that individuals with autism would not elect to express their thoughts, feelings, and emotions through

autobiographical writings. As well as displaying impairments in aspects of the self (including self-awareness, self-referential cognition, and introspection), individuals with autism characteristically have written and verbal communication difficulties. Despite this, more than 50 autobiographies and memoirs of individuals with autism have been published, and several more appear online. Autobiographical writings have also appeared in the form of entries in chat rooms and blogs, as well as letters or articles. They are clearly a popular method of expression for individuals with autism.

Autobiographical writings have provided researchers, clinicians, and the general public with comprehensive and insightful accounts of living with autism from a personal perspective. One of the most well-known individuals with autism to have produced autobiographical works is Temple Grandin – a highly successful and articulate professor of animal science, who was diagnosed with autism as a child. These writings include her autobiography *Emergence* (which was edited by a children's writer) in addition to a number of articles that were independently written (e.g., Grandin 1984). Marked differences between her entirely self-produced and her externally edited autobiographical writings have been noted, the former exhibiting a higher number of written characteristics that are typical of an individual with autism. These include unexplained changes in topic and a failure to provide readers with pertinent background information that is necessary to fully understand the text (see Happé 1991, for an analysis of this work). Sacks (1995) referred to Grandin's *Emergence* as "unprecedented," as this was the first "inside narrative" of autism.

Another high-functioning female autobiographer who has been diagnosed with autism is Donna Williams. As well as authoring a number of autobiographies (including *Nobody Nowhere* and *Somebody Somewhere*), Williams shares her autobiographical writings through an online blog, which provides regular autobiographical entries. In recent years, several other high-profile individuals with autism have elected to use online blogging as a means of communicating their

autobiographical writings. These include Daniel Tammet (an adult with autism famed for his remarkable memory abilities), who has also published a memoir of his life, *Born on a Blue Day*. Blogging has become an increasingly popular tool for individuals with autism in recent years and, as they are easily updatable, blogs are a useful and rapid means of communicating the current thoughts of individuals with autism.

Although the published autobiographical writings and blogs of high-functioning adults with autism have provided an insight into the experiences of autism at one extreme of the autism spectrum, autobiographical writings have also stemmed from individuals with autism that have more disabling communication impairments. Tito Mukhopadhyay is a writer and poet who is non-verbal, but communicates through his sophisticated writings. He therefore allows readers a window onto life with autism and severe communication difficulties. He is also one of the few individuals with autism to have produced writings as a child, writing *The Voice of Silence* at the age of 8 and *Beyond the Silence* at the age of 11. Tito's autobiographical writings are largely his own work and, to ensure the integrity of his writings, all changes or additions by editors or cowriters have been carefully and clearly noted in the text.

In between these two extremes of the autism spectrum are individuals such as David Miedzianik and Barry (both of which are documented in Happé 1991), who perhaps represent a more typical existence on the (verbal) autism spectrum. Barry's letters to a correspondent were entirely self-motivated works that received no external editing. They displayed features of autism including social naivety, perseveration on topics, the use of parroted material, and the introduction of topics without providing sufficient background information for readers. In contrast, David Miedzianik's autobiographical writings (despite flitting between one subject to another) demonstrate consideration for the reader's state of knowledge, usually introducing information with an explanation. As with the majority of autobiographical writings in autism, these two cases clearly demonstrate the striking range of abilities (and disabilities) found within the autism spectrum.

Researchers and clinicians have used the autobiographical writings of individuals with autism to gain an insight into the mind of individuals with this disorder. Autobiographical writings can provide readers with personal accounts of the core symptoms of autism (for example, specifying real-world instances of social and communication difficulties, or repetitive behaviors, interests, and activities). In particular, they provide a stark reminder of the different manifestations of the key signs and symptoms of autism in different individuals. This can allow professionals to better understand the specific needs of individuals with autism. The actual writings themselves can also provide an insight into the features of the disorder. For example, the writings of individuals with autism often demonstrate commonly noted characteristics of autism including perseveration on topics of interest, unusual changes in topic, a lack of empathy, and a failure to appreciate the prior knowledge of the reader. Writing about personal thoughts, feelings, and experiences may be a medium of choice for individuals with autism as this removes the need for social interactions and spoken communication. This is especially true of online blogging and chat rooms, which have become a very popular means for sharing autobiographical writings and experiences in recent years. This vehicle of communication has been used to help typical individuals understand more about autism. It can also provide a forum for individuals with autism to discuss their interests and may allow an insight into the strengths and weaknesses of the autism community.

Future Directions

Although researchers have attempted to study, and make inferences from, the autobiographical writings of individuals with autism, there are many difficulties faced when interpreting these writings. First, such an analysis often requires a subjective approach to interpretation. Qualitative researchers must make judgments about the underlying motivations and intentions of individuals with autism, which may be erroneous and lead to both false-

positive and false-negative conclusions (see Happé 1991, for a discussion). Using a more quantitative approach, researchers have used content analytic techniques to examine the frequency of specific terminology or phrases within autobiographical writings (e.g., Crane and Goddard 2008; Crane et al. 2010). This technique may be overly superficial and especially problematic given the language and communication atypicalities noted in individuals with autism. Future research should attempt to merge both qualitative and quantitative approaches to the assessment of autobiographical writings in autism.

A second issue regards how the autobiographical writings of individuals with autism are typically from a very able and high-functioning subgroup of individuals with the disorder. Although some published works are from individuals with severe communication difficulties (e.g., Tito Mukhopadhyay), those who produce autobiographical writings must have a relatively high degree of written language abilities. Not only are the majority of these individuals among the most verbally fluent and intellectually able persons on the autism spectrum, their autobiographical writings have tended to make them celebrities within the autism field. As such, their experiences (especially in their latter years) are perhaps somewhat atypical of the everyday experiences of individuals with autism. Problems therefore arise regarding the generalizability of their writings, and it is important for future research to examine a wide range of autobiographical writings, from individuals across different levels of the autism spectrum. Although researchers have explored online writings of individuals with autism (e.g., Jones et al. 2001), which affords an insight into the experiences of a broader range of individuals with autism, questions concerning authenticity arise.

Third, there is a lack of an appropriate comparison group against which to compare the autobiographical writings of individuals with autism. Most published autobiographical writings are from typical adults, usually those in the public eye with rather unusual lives (e.g., politicians, celebrities) or from professional writers. These do not provide suitable comparisons for the

autobiographical writings of individuals with a neurodevelopmental disorder. Some researchers have compared the autobiographical writings of adults with autism with those of adults with schizophrenia (see Happé 1991, for a comparison of Grandin's autobiographical writing with that of a female with schizophrenia), but these comparisons are limited. The selection of a suitable comparison group is also confounded by the lack of interest in works of fiction that is commonly noted in individuals with autism (Happé 1991). As this group may not read fictional works to the same degree as typical adults, this may influence the content and structure of their autobiographical writings. These difficulties mean that it is problematic to draw inferences on the typicality or atypicality of the autobiographical writings of this group, or to determine how they are similar to or different from the writings of individuals without autism. The selection of a range of appropriate comparison works is crucial for future research in this area.

Another important direction for future research is to establish the degree to which the autobiographical writings of individuals with autism are the work of the individual themselves. Published autobiographical writings (in particular, life stories, memoirs, and autobiographies) are often subject to high levels of editing or rewriting by publishers, editors, or cowriters. Indeed, Temple Grandin's autobiographical work *Emergence* was cowritten with a children's writer who rewrote and formatted sections of the book and structured it to make it easier to read. This significantly limits the conclusions that can be drawn from the autobiographical text itself. Indeed, Grandin's autobiographical writing *My Experiences as an Autistic Child* is markedly different to *Emergence* and displays several characteristics that are typical of an adult on the autism spectrum (e.g., switching between topics, failing to provide the reader with pertinent background knowledge regarding a topic). Analysis of writings that clearly delineate the text composed by individuals with autism and that inserted or changed by editors or cowriters is important for future research, as is the analysis of online writings, which tend to be solely the work of the individual with autism (without subsequent editing).

Future research could also consider gender differences in the autobiographical writings of individuals with autism. Despite a higher number of males than females being diagnosed with autism, it appears that more women with autism express themselves in writing and publish their work. Future work should therefore aim to compare the autobiographical writings of males and females with autism, to ascertain whether there are similarities or differences in the expressions of these writings.

A final point to note regarding the autobiographical writings of individuals with autism concerns their recall of personal experiences. Research on autobiographical memories has shown that memories of personal events are not veridical representations of the past – they are reconstructions of experiences. As such, doubts can be raised concerning the accuracy of the events and experiences referred to in the autobiographical writings of individuals with (and without) autism. This is an important factor to take into account when evaluating, and drawing inferences from, the autobiographical writings of individuals with autism (as well as the writings of typical comparison adults).

Autonomic Nervous System

Jonathan Kopel

Texas Tech University Health Sciences Center (TTUHSC), Lubbock, TX, USA

Synonyms

Central nervous system (CNS); Peripheral nervous system (PNS)

Definition

The autonomic nervous system (ANS) coordinates the body's fight or flight and rest and digest response through the central and peripheral nervous systems (Rees 2014). Specifically, the ANS maintains homeostasis and adapts physiological, psychological, and behavioral responses to external stressors (Klusek et al. 2015; Rees 2014). Dysfunction of the ANS increases the risk of numerous psychological disorders including panic disorder, anxiety, post-traumatic stress disorder (PTSD), and schizophrenia (Klusek et al. 2015). Several studies showed Autistic Spectrum Disorder (ASD) children revealed diminished parasympathetic response, autonomic response, and vagal tone (Benevides and Lane 2013; Järvinen et al. 2015; Klusek et al. 2015). Furthermore, ASD children exhibited a variety of sensory deficits affecting their capacity to feel and integrate emotions (Järvinen et al. 2015; Legiša et al. 2012). In addition, ASD children showed hyperarousal and high sensitivity to facial expressions, particularly those with fearful, happy, or no emotion (Järvinen et al. 2015). However, the ANS dysfunctions among ASD patients occurs only during goal-directed activities and disappears under normal physiological conditions (Benevides and Lane 2013). As a result, further investigation is needed to elucidate the coordinated interactions between sympathetic and parasympathetic systems, and the behavioral and physiological differences seen in ASD patients.

Aversive/Nonaversive Interventions

Michael D. Powers
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Aversive and nonaversive interventions refer as much to a dynamic yet functional definition of both terms as to a set of intervention procedures. From a technical point of view, an aversive intervention involves the application of an aversive stimulus. This would include a noxious event that serves as a punisher when it follows behavior, one that evokes a behavior that has terminated the noxious stimulus in past circumstances, or one that functions as a reinforcer when it is removed after the occurrence of a behavior (Cooper et al. 2020). A nonaversive intervention involves the application of positive reinforcement and/or extinction contingencies as a consequence to a behavior or alteration of the intensity, duration, or magnitude of a behavior contingent upon the removal or presentation of an antecedent stimulus.

Historical Background

While treatment in autism has, over the years, had many controversies, perhaps none has been so heated as the discussion of the viability and

appropriateness of aversive and nonaversive procedures to treat a variety of problems common to the disorder (and to those with other neurodevelopmental disorders as well). These controversies have pitted, in somewhat of a dichotomous fashion, empirical science against social validity. The result was at once unfortunate and the stimulus for a paradigmatic shift. When in its relative infancy, the science of the experimental analysis of behavior served a very important function: to prove that even the most recalcitrant of human behaviors are subject to the laws of learning and can be improved upon. For generations of clinicians raised on the belief that change was only possible in small increments for those severely affected by autism and then only through rather drastic psychopharmacologic interventions, the opportunity to demonstrate progress in reducing self-injury, aggression, and other destructive behaviors as well as to increase prosocial, adaptive behavior was a breakthrough. Applications of more basic operant conditioning principles such as positive and negative reinforcement, extinction, and punishment were tactics of choice during this period. Indeed, clinical significance was often defined only in terms of the magnitude of behavior reduction (the end product) but rarely so by the means of reduction.

As the 1960s progressed through to the late 1970s, however, means of intervention appropriately became a more prominent consideration. The seminal work on social validity by Kazdin (1977) and Wolf (1978) reshaped the narrative around three key points: not only must the outcome of intervention be socially valid but also the target of intervention (behavior to be changed) and also the means to achieve that outcome. As a construct, social validity imposes the requirement that all factors be considered before, during, and after treatment. This demand served several important functions. It posed the important question, "socially valid for whom?" Were targets, procedures, and outcomes socially valid for the client, the family, and institutionally based caregivers? Social validity also raised the question of relativity. At different points in time, for different clients, and under particular circumstances, a treatment procedure or outcome might

or might not be acceptable. But very importantly, at its base, the question of social validity also raised the issue of the generalizability of behavior change. While behavior analysis had evolved very good technologies of generalization and maintenance (Horner et al. 1988), things did not always work out as planned. So-called treatment failures continued to occur, often under the contingencies of more remote or diverse (and sometimes less well-understood) events. By imposing the demand to assess for social validity, interventionists had a tool to begin to predict potential functional relationships between change agents and the consumers of change and to begin to modify those contingencies that might interfere with long-term maintenance and generalization.

Within the span of a few years, however, a number of flash point events occurred that sharpened the issues concerning treatment of those whose autism placed themselves, and others, at the greatest risk. Highly publicized reports of the deaths of clients in the care of otherwise well-known residential programs following the use of contingent aversive procedures (e.g., white noise) changed the conversation from one of science alone to a discussion of human dignity and the right to effective treatment. Suffice it to say that while at times mean-spirited, personal, and derogatory, the power of the objectivity of science won out. Indeed, not only did the National Institutes of Health fund a number of collaborative research centers with the mandate to investigate and develop effective interventions that were non-aversive, but the NIH later convened a consensus conference (National Institutes of Health 1991) in order to issue guidelines for the use of behavior reduction procedures (including punishment strategies) when treating destructive behavior in those with developmental disabilities. The efforts of established collaborative research centers, other scientists working in basic and applied settings, and the general understanding of the effects (and negative effects) of punishment have led over the past 20 years to a highly developed, evolving, evidence-based technology of behavior change based upon the use of antecedent and consequent control procedures that do not involve the use of aversive stimuli. To be certain, the controversy

has not ended entirely, as those who empirically demonstrate the effective use of punishment procedures *as a component of a comprehensive treatment package* would argue (Axelrod 1990). But, as importantly, the exceptional science being developed to understand the often complex functional motivators behind severe behavior continues as well and is especially visible in the efforts of those promoting positive behavior support initiatives in public schools.

Rationale or Underlying Theory

Given the extensive research base for both aversive and nonaversive interventions, it is reasonable to conclude that considerations about each are evidence-based. The important considerations, however, lie in the issue of negative effects and generalizability of effects. Both sets of procedures are based on the principles of operant conditioning earlier described by Skinner, with many decades of subsequent and substantive empirical extensions of that work. What has evolved over the years is a toolbox of intervention strategies, many working best as part of multi-component procedures. While there may well be occasions for which a punishment procedure – in combination with positive reinforcement procedures designed to increase functionally equivalent, alternative prosocial behavior – is the least restrictive intervention option, intervention based on punishment alone is rarely advised.

Nonaversive interventions are broadly organized around antecedent strategies (those that occur before the problematic behavior is emitted), with the intention of altering the stimulus control and reinforcing value of the existing antecedent “triggers” for the behavior. Consequent procedures are those delivered after behavior has been demonstrated. They can include reinforcement-based procedures, extinction, and variants of interruption and redirection. In contrast, aversive interventions involve the application of an aversive or unpleasant stimulus immediately following the problem behavior, designed to discourage future occurrence of the behavior. In all cases, however, whether an intervention is aversive or

reinforcing to a client is a functional question. If the application of a stimulus immediately following demonstration of a specific behavior increases the probability of that behavior occurring, the stimulus was reinforcing. If presentation of the stimulus immediately following the behavior reduces the likelihood of behavior reoccurrence, then the stimulus was aversive. Referring back to the discussion of social validity earlier, what is aversive to one person may be reinforcing to another. The only solution is to assess functionally before and during treatment implementation.

Ultimately, the rationale about which intervention strategies to employ in a particular case is a functional one, clarified by a thorough functional behavior assessment/analysis and subjected to rigorous outcome evaluation. In the final analysis, intervention must be effective, that is, it must be successful in its outcome and have minimal or no negative effects associated with it. Treatment strategies that are socially valid and empirically based will best serve the interests of persons with autism and related neurodevelopmental disorders.

Goals and Objectives

The selection of intervention strategies is based on behavioral function, not form. Function can be described in several ways. For example, behavior can serve to access positive reinforcement in the form of social attention or access to preferred materials. The behavior can be functionally reinforced by its ability to terminate an aversive or unpleasant event (negative reinforcement). These functions can be observed in the presence of others or when the client is alone. In this latter case, we suggest that the behavior can be maintained by the positive or negative reinforcing contingencies of sensory stimuli impinging on the client. In all cases, the stated goal of intervention should be to improve the behavior of the person with autism by teaching appropriate replacement skills while simultaneously reducing or eliminating the behavior that is problematic or that interferes with more adaptive functioning. Specific procedures to accomplish this are discussed below.

Treatment Participants

Treatment procedures for any given client are selected based upon the results of the functional assessment/analysis but may be modified to address the specific target behaviors selected, the learning history (history of reinforcement) of the client with the particular behavior, and the availability of resources and competencies of intervenors. Consideration is also given to such factors as severity, duration, pervasiveness, and frequency of the target behavior when determining priorities for intervention.

Treatment Procedures

Treatment procedures for nonaversive interventions can be broadly divided into two groups: antecedent interventions that occur prior to the behavior and consequent procedures that are implemented after the behavior has been emitted. Both seek to reduce the likelihood of behavioral expression in the future by emphasizing the use of positive reinforcement procedures as a key or collateral component of the treatment package. Most importantly, all treatment should be preceded by a thorough functional behavior assessment or analysis in order to determine which stimuli in the environment exert control over the target behavior.

Antecedent procedures include errorless learning, whereby the student is prompted to the correct response immediately after the presentation of the request; interspersing mastered or easy tasks with difficult tasks in teaching (Weber and Thorpe 1992); the use of choice in the selection of tasks and reinforcers (Dyer et al. 1990); reducing the information-processing demands of the task or providing an alternative mode of task presentation; use of a high-probability request sequence (Zuluaga and Normand 2008); functional communication training (Carr and Durand 1985); stimulus change procedures, whereby a novel stimulus that is not an antecedent or a consequence to the behavior is interjected into a behavioral sequence, interrupting the response-reinforcer relationship (Carr et al. 1990); and environmental modifications such as use of visual schedules, curriculum

adjustment, etc. (Flannery and Horner 1994; Kern and Dunlap 1998).

Consequent procedures with demonstrated efficacy include positive reinforcement, differential reinforcement, and its variants (differential reinforcement of other, incompatible, high rates or alternative behavior); response interruption and redirection (Underwood et al. 1989); extinction (Lerman and Iwata 1996); and noncontingent reinforcement, whereby reinforcing stimuli are provided to a client independent of the client's behavior (Carr et al. 2009).

Aversive stimuli are noxious events that serve as punishers when following a behavior, evoke a behavior that has terminated the noxious stimulus in past circumstances, or function as a reinforcer when removed after the occurrence of a behavior (Cooper et al. 2020). While the function of an aversive stimulus is always to cause the cessation of a behavior, its forms are virtually limitless (Repp and Singh 1990) and have included smelling aromatic ammonia, contingent water mist to the face, the application of "white noise," and electric shock. It is noteworthy that while the NIH consensus conference clearly emphasized the importance of using treatment procedures based on positive behavioral supports, it also provided clear guidelines for the use of punishment procedures when they might be deemed clinically necessary.

Efficacy Information

The efficacy of antecedent strategies to treat behavior problems has been well documented in the research literature, and several in particular have been identified as evidence-based procedures (Cooper et al. 2020; Powers et al. 2011). It is important to remember, however, that the use of an antecedent (or any other) strategy does not guarantee success. Rather, the use of the procedure must be based on the results of the functional behavior assessment/functional analysis, must be implemented with fidelity, and must be evaluated accurately and objectively. Violation of any of these tenets can (and likely will) reduce the efficacy and efficiency of the correctly chosen treatment strategy.

Outcome Measurement

Objective and reliable measurement of treatment effects and outcomes is essential to the correct use of any procedure designed to increase desirable behavior or to reduce problem behavior. Fortunately, the use of single-subject experimental designs (SSEDs) has predominated in the literature (Kazdin 1982), establishing a robust arsenal of potential designs for outcome measurement. When well used, SSEDs provide excellent internal and external validity, support the development of reliable observations, and ultimately contribute to the serial replication of findings. To this latter point, the aggregation of large numbers of individual studies, each with a small subject pool, can generate strong findings of efficacy (Reichow et al. 2011).

Qualifications of Treatment Providers

While certainly effective when used correctly, the technology of intervention requires training in the principles and strategies of applied behavior analysis. Obviously, with behavior problems of greater significance (e.g., where personal safety of the client or others is at risk and where health status can/may be compromised), the demand for greater levels of sophistication and competency is critical. At a minimum, supervision of assessment and treatment protocols by an individual with Board Certification as a Behavior Analyst (BCBA) or by a clinician with equivalent training and experience would be appropriate. In cases where more extraordinary interventions are necessary or where the risk of harm is greater, it is strongly advisable to have all clinical aspects peer reviewed and vetted by a human rights committee.

Avoidant Personality Disorder

Daniel F. Becker
Department of Psychiatry, University of California, San Francisco, USA

Synonyms

[Anxious Personality Disorder](#)

Short Description or Definition

In the most recent *DSM* revision, the *DSM, Fifth Edition (DSM-5)*; American Psychiatric

Association [APA] 2013), AVPD is classified as a personality disorder and is described as “a pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation that begins by early adulthood and is present in a variety of contexts” (p. 673). As for all personality disorders, “this pattern of inner experience and behavior... deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible,... is stable over time, and leads to distress or impairment” (p. 645).

Categorization

As indicated above, AVPD is classified within the Personality Disorders section in *DSM-5*. Based largely on an earlier, theoretically derived construct (Millon 1981), AVPD first appeared as a diagnostic entity in *DSM, Third Edition (DSM-III*; APA 1980). This category grew from a trifurcation of the *DSM, Second Edition (DSM-II*; APA 1968) diagnosis, schizoid personality – which described individuals with “shyness, oversensitivity, seclusiveness, avoidance of close or competitive relationships, and often eccentricity” (p. 42). The broader *DSM-II* schizoid personality construct was, in *DSM-III*, subdivided into a more narrowly defined schizoid personality disorder, as well as schizotypal and avoidant personality disorders. Schizotypal personality disorder was thought to describe those individuals who had previously been diagnosed with borderline schizophrenia and encompassed the eccentricity noted in the *DSM-II* description. The distinction between *DSM-III* avoidant and schizoid personality disorders was construed as centering on whether or not the individual had the motivation and capacity for emotional involvement with others (APA 1980; Millon 1981).

Beginning with *DSM-III*, personality disorders were placed on axis II within a recommended “multiaxial” approach to psychiatric diagnosis; axis II encompassed specific developmental disorders as well as personality disorders and was felt to be useful in ensuring that “consideration is given to the possible presence of disorders that are frequently overlooked when attention is directly toward the usually more florid Axis

I disorder” (p. 23). Beginning with *DSM, Third Edition, Revised (DSM-III-R; APA 1987)*, AVPD was placed in the cluster C subcategory of personality disorders, which are characterized by “anxious or fearful” (p. 337) clinical presentations. *DSM-III-R* aligned AVPD with the clinical concept of “phobic character” (p. 429) and no longer suggested that it needed to be mutually exclusive with schizoid personality disorder. In *DSM, Fourth Edition (DSM-IV; APA 1994)*, AVPD remained in cluster C, along with dependent and obsessive-compulsive personality disorders, as it does now in *DSM-5*. It is worth noting, however, that the multiaxial system has been eliminated in the current diagnostic manual – and personality disorders are now classified alongside all other relevant diagnoses.

Although initially formulated in *DSM-III* as a monothetic criterion set – requiring, for the diagnosis, all five possible symptom criteria – subsequent revisions have constructed AVPD as a polythetic set, requiring any four of seven possible criteria. Each successive revision – from *DSM-III* to *DSM-III-R*, and from *DSM-III-R* to *DSM-IV* – involved adding, deleting, and rewording various criteria. These changes have been based, in part, on empirical evidence (Baillie and Lampe 1998; Becker et al. 2009; Grilo 2004; Hummelen et al. 2006). No further changes were made to the AVPD criteria in the transition from *DSM-IV* to *DSM-5*.

Epidemiology

Investigations in clinical samples have shown AVPD to be among the most frequently diagnosed personality disorders (Alnæs and Torgersen 1988; Stuart et al. 1998). Although *DSM-III* and *DSM-III-R* had indicated only that AVPD is “apparently common” (APA 1980, p. 323, 1987, p. 352) in the general population, and *DSM-IV* stated that the general prevalence of this disorder is between 0.5% and 1.0% (APA 1994), *DSM-5* cited a prevalence of 2.4% (APA 2013). However, two large, community-based studies – using *DSM-III-R* (Torgersen et al. 2001) and *DSM-IV* (Ekselius et al. 2001) criteria – both yielded much higher rates of 5.0% and 6.6%, respectively. In the

former study, AVPD was more prevalent than any other personality disorder; in the latter study, it was the second most prevalent among these disorders. Ekselius et al. (2001) observed generally that individuals with personality disorders more often were younger, were students or unemployed, received psychiatric treatment, and lacked social supports.

Natural History, Prognostic Factors, and Outcomes

Unfortunately, relatively few studies have directly examined AVPD (Alden et al. 2002). Instead, most have considered AVPD along with other personality disorders – in the service of understanding personality pathology more broadly or within the context of studying the effects of comorbid AVPD on axis I psychiatric disorders. As a result, relatively little is known about the natural history and progression of AVPD. *DSM-5* (APA 2013) notes that avoidance often begins in childhood with shyness – but that, while shyness in most individuals dissipates with age, those who progress to develop AVPD will often become increasingly shy and avoidant during adolescence and young adulthood. Evaluation of the childhood antecedents of AVPD has shown that adults with AVPD – in relation to relevant clinical comparison groups – report poorer athletic performance during childhood and adolescence, less involvement in hobby activities during adolescence, and diminished adolescent popularity (Rettew et al. 2003).

Personality disorder stability has been shown, in general, to be modest; for AVPD, 2-year remission rates as high as 50% have been reported by the Collaborative Longitudinal Personality Disorders Study (Grilo et al. 2004). These investigators have also suggested that personality disorders are hybrids of traits and symptomatic behaviors, with the former being more stable. The interaction of these elements over time helps to determine diagnostic stability. For AVPD, the trait-like criteria – which are the most prevalent and stable – include regarding oneself as socially inept, feeling inadequate compared to others, and wanting evidence of being liked before making social contact

(McGlashan et al. 2005). These observations suggest that the course, persistence, and severity of AVPD – as for all personality disorders – depend upon an interaction of personality traits and the individual's behavioral adaptations to these traits (Lilienfeld 2005). The functional consequences of AVPD are generally significant – having a more profound effect on psychosocial adaptation than, for instance, major depression (Skodol et al. 2002).

Clinical Expression and Psychopathology

In a seminal description of the AVPD construct, Millon (1981) describes four levels of clinical data that may help in the diagnosis: (1) behavioral features (e.g., shyness or timidity, apprehensiveness or guardedness, touchiness, evasiveness, restraint of emotional expression, and physical underactivity with periodic bursts of fidgeting); (2) self-descriptions or complaints (e.g., feeling anxious or ill-at-ease, viewing others as critical or humiliating, and uncertainty about one's self-worth); (3) interpersonal coping style (e.g., anticipation of censure and derision, minimizing involvements that might reactivate or duplicate past humiliations, and diminishing the importance of interpersonal relationships); and (4) inferred intrapsychic dynamics (e.g., conflict between mistrust and the desire for affection, tension between derogation by others and self-deprecation, and tension between the surrounding distress and the emptiness within).

As noted above, *DSM-5* (APA 2013) requires four of seven possible diagnostic criteria:

- Avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection.
- Is unwilling to get involved with people unless certain of being liked.
- Shows restraint within intimate relationships because of the fear of being shamed or ridiculed.
- Is preoccupied with being criticized or rejected in social situations.
- Is inhibited in new interpersonal situations because of feelings of inadequacy.
- Views self as socially inept, personally unappealing, or inferior to others.
- Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing.

Given the polythetic nature of this and other *DSM-5* personality disorder constructs, psychometric studies – especially those demonstrating a simple factor structure and good internal consistency – have played a key role in establishing construct validity of AVPD. Overall, such studies have demonstrated high internal consistency and a unidimensional structure for the AVPD criterion set adopted in *DSM-IV* and maintained in *DSM-5* (Becker et al. 2009; Grilo 2004; Hummelen et al. 2006).

Evaluation and Differential Diagnosis

Although few data exist regarding the diagnostic process as it relates to AVPD, some evidence has been offered with regard to other personality disorders (Zimmerman and Mattia 1999) or to personality disorders more generally (Zimmerman 1994). Such disorders tend to be diagnosed relatively infrequently within the clinical interview process as compared to when semistructured diagnostic interviews are utilized (Zimmerman and Mattia 1999). This may be due to a general inattention to personality disorder in many clinical settings – or, perhaps, to the polythetic nature of these diagnoses. Although it is therefore preferable that a semistructured diagnostic interview be used in evaluating patients for personality disorders, there is considerable variability among such instruments. Another concern about the assessment process is that the diagnosis of personality disorders is likely to be biased by the patient's acute clinical state (Zimmerman 1994).

With regard to differential diagnosis, consideration should be given especially to social anxiety disorder (social phobia), which is classified as an anxiety disorder in *DSM-5*. Its essential feature is

“a marked... fear or anxiety of social situations in which the individual may be scrutinized by others” (APA 2013, p. 203); social anxiety disorder is therefore phenomenologically similar to AVPD. Indeed, genetic studies have suggested that there is a common genetic vulnerability underlying both disorders (Reichborn-Kjennerud et al. 2010).

Consideration should be given as well to agoraphobia, which is another *DSM-5* (APA 2013) anxiety disorder characterized by avoidance. Finally, with regard to differential diagnosis, some other personality disorders should be considered. These include the other cluster C disorders, characterized by anxiety and fearfulness – especially dependent personality disorder, which can similarly be marked by feelings of inadequacy, sensitivity to criticism, and need for reassurance – as well as the phenomenologically reminiscent, but somewhat more disabling, cluster A conditions: schizoid, schizotypal, and paranoid personality disorders (APA 2013).

Treatment

Studies have shown that psychotherapeutic intervention is the treatment of choice for personality disorders in general – and that this conclusion holds specifically, as well, for AVPD (Verheul and Herbrink 2007). In particular, psychodynamic and cognitive-behavioral therapies have proven effective – especially as individual outpatient modalities but also in group settings and within structured treatment contexts. There is less evidence in support of pharmacotherapeutic intervention, although some have suggested treatment with antidepressant medications – such as selective serotonin reuptake inhibitors – based, in part, on the potential relationship between AVPD and social anxiety disorder (Deltito and Stam 1989; Kapfhammer and Hippus 1998; Ripoll et al. 2011).

Ayres, A. Jean

Winifred Schultz-Krohn
Department of Occupational Therapy, San José
State University, San José, CA, USA

Name and Degrees

A. Jean Ayres, PhD, OTR, FAOTA.

Graduated with a BA in Occupational Therapy from University of Southern California in 1945.

Graduated with an MA in Occupational Therapy from University of Southern California in 1954.

Graduated with a PhD in Educational Psychology from University of Southern California in 1961.

Major Appointments (Institution, Location, Dates)

Faculty member in the Department of Occupational Therapy at the University of Southern California (USC) from 1955 to 1964.

Professor in the Department of Special Education at the USC from 1966 to 1977.

Adjunct faculty member in the Department of Occupational Therapy at USC from 1976 to 1984 while running her clinic devoted to serving children with sensory integrative disorders.

Major Honors and Awards

Awarded Fellow of the American Occupational Therapy Association (FAOTA).

Awarded the Eleanor Clark Slagle lectureship in 1963.

Received the highest honor from the American Occupational Therapy Association in 1965, the Award of Merit.

Named as one of the Outstanding Educators of America in 1971.

Charter member of the American Occupational Therapy Association Academy of Research.

Honored by the American Occupational Therapy Association in 1988 with the initiation of the award entitled the A. Jean Ayres Award for Theory Development and Application.

Landmark Clinical, Scientific, and Professional Contributions

Dr. A. Jean Ayres originated the Ayres Sensory Integration theory. She developed the theory into principles of intervention and assessment instruments including the Southern California Sensory Integration Tests (SCSIT) and then revised this instrument as the Sensory Integration and Praxis Tests (SIPT). As an occupational therapist, she introduced the profession to this client-centered, neuroscience-based theory and practice approach to support children with sensory integration disorders/sensory processing disorders.

Short Biography

Biography: A. Jean Ayres

Dr. A. Jean Ayres was born in 1920 in Visalia, CA, and reportedly had challenges learning as a young child, particularly processing various types of

sensory information. She attended the University of Southern California and successfully completed her BA in Occupational Therapy in 1945, her MA in Occupational Therapy in 1954, and her PhD in Educational Psychology in 1961. She completed her postdoctoral training at University of California, Los Angeles (UCLA), Brain Research Institute working with the leading neurophysiologists at that time. Her clinical skills in occupational therapy, with a foundation in the engagement in purposeful activity, and her neuroscience training provided her with the unique perspective to understand how the nervous system can influence functional behaviors.

Dr. Ayres had a long history in academia and was a faculty member in the Department of Occupational Therapy at the University of Southern California (USC) from 1955 to 1964. She then was a professor in the Department of Special Education at the USC from 1966 to 1977. She returned as an adjunct faculty member in the Department of Occupational Therapy at USC from 1976 to 1984 while running her clinic devoted to serving children with sensory integrative disorders.

Dr. Ayres' work as an occupational therapist with children who had learning disabilities and sensory processing challenges served as the impetus for her conceptualization of sensory integrative dysfunctions. She encountered individuals who would complain of how painful it was to have their hair brushed or to wear specific fabrics. This furthered her research endeavors in the area of sensory integration dysfunction and theory development. Her development of the theory of sensory integration expanded, and her numerous publications, books, and approximately 50 scholarly articles provided further evidence of this phenomenon. As a clinician, researcher, and academic, Dr. Ayres recognized the need to establish a mechanism to identify sensory integrative dysfunction and link theory to practice. She developed the Southern California Sensory Integration Tests (SCSIT) in 1972 with intensive training courses on theory, test administration, and interpretation seminars. As the research and theory developed further, Dr. Ayres revised the assessment tool and the Sensory Integration and Praxis Test was published in 1989.

As an occupational therapist, Dr. Ayres sought to support children and provide intervention directed not only to fostering improved functional skills but to develop an explanation regarding the challenges faced by children with sensory integrative disorders. Her scholarship, clinical expertise, and dedication were recognized in several arenas. She was awarded the prestigious Eleanor Clark Sagle lectureship in 1963 by the American Occupational Therapy Association. In her address, she described the theory and practice of sensory integration and how this unique perspective supports participation in everyday tasks. Her substantial contributions to advance the profession of occupational therapy were further recognized when she received the Award of Merit in 1965. This is the highest honor awarded by the American Occupational Therapy Association. In 1971, Dr. A. Jean Ayres was named as one of the Outstanding Educators of America. Dr. Ayres was a charter member of the Academy of Research of the American Foundation of Occupational Therapy, and in 1988, the A. Jean Ayres Award for Theory Development and Application was established in her honor by the American Foundation of Occupational Therapy.

Dr. A. Jean Ayres married Franklin Baker in 1969. She died on December 16, 1988, from complications of cancer. Franklin Baker died on September 2, 1989.

Babbling

Kelly Macy

Department of Communication Sciences, The
University of Vermont, Burlington, VT, USA

Definition

Babbling can be defined as a type of prelinguistic, non-cry vocalization, which typically emerges by 6 or 7 months of age with repetition of the same consonant vowel (CV) syllable (“ba ba”) (Johnson 2008; Paul 2007). This can also be referred to as *canonical babbling* (Oller et al. 1998) or *reduplicative babbling* and is an important part of the developmental process of emerging speech and language. Utterances produced with full stop consonants such as /p/, /b/, /t/, and /d/ and vowels are most common at this stage, resulting in utterances such as /baba/ and /dIdI/ (“dee dee”). *Variegated babbling*, where successive syllables are not identical, begins to appear between 6 and 10 months of age (Paul 2007; Proctor 1989). This consists of a variety of CV and consonant-vowel-consonant (CVC) syllables that are not identical (“pa ta”). By the end of the first year, babbling should begin to imitate the

intonation and prosody of adult speech. This is also referred to as *jargon babble* (Paul 2007).

Historical Background

Research findings from the past several decades on the nature of babbling have documented a shift in the scientific and clinical evidence regarding the connection between babbling and speech and language acquisition. Early literature reported a weak relationship between babbling and early speech development (e.g., Jakobson 1941; Lenneberg 1967). It was not viewed as being composed of linguistic units but rather a biomechanical action where the infant lacks control over the sounds produced. This view, known as the motoric hypothesis, asserts that babbling is just a by-product of motor development. There was also a common misconception that babbling ended prior to the emergence of first words. In recent decades, however, there has been a shift to a linguistic hypothesis, which maintains that babbling has a neurolinguistic foundation and there is a continuity between babbling and early speech forms (Petitto et al. 2000; Vihman et al. 1986). This shift in opinion is based on a strong body of research suggesting that babble and speech share

phonological characteristics within target languages and within individual children (Whitehurst et al. 1991).

Current Knowledge

Progression and presentation of babbling, as well as the acquisition and use of speech and language, can vary greatly among children with autism. It is possible for babbling and other communication milestones to develop normally in this population but then later regress. Approximately 25–30% of children with autism exhibit babbling and begin to say words but then stop speaking between the ages of 15 and 24 months (Johnson et al. 2007). This has been documented by home videos of children who were typically developing, children with early-onset autism, and children with regressive-type autism and reported in a study by Dawson and Werner (2005). They found that the regressed children used complex babbling and words significantly more often than the early-onset children did. Furthermore, the children with regressive-type autism used complex babble nearly twice as often as typical children.

Certain children who present with developmental delays, including those with early-onset autism, may be unusually quiet and make few vocalizations. Others may produce atypical vocalizations such as humming and grunting, and fail to exhibit the typical canonical and variegated babbling within the expected time frames (Johnson 2008). Lack of canonical babbling by 10 months of age has been shown to predict delays in language development in the second year of life (Oller et al. 1998). Current research with infants who are typically developing and those with developmental delays has supported the continuity between babbling and its relationship to patterns in early speech (Davis and MacNeilage 1995; Mitchell 1997).

Typically developing infants exhibit a back-and-forth type pattern of babbling and apparent listening that is coordinated with the caregiver's speech and is similar to the conversational turn-taking that is used by older children (Johnson 2008). Children with autism may continue to

vocalize as if they are not aware of the caregiver's speech, with overlapping vocalizations and lack of eye contact. Parents may report that their child does not seem to recognize their voice or notice when they enter or leave the room. At the jargon babble stage near 1 year of age, they may lack inflection and prosody that is common by this stage.

Since differences and delays in babbling are frequently found in children with autism, an analysis of the child's pre-speech vocalizations by a speech-language pathologist may help to identify children who are at risk (Mitchell 1997). Children who exhibit a loss of babbling should also be referred for an evaluation, as this is a serious red flag. Hearing loss, delayed motor development, and lack of social interactions may also contribute to delays in babbling. For children who were born prematurely, corrected gestational age (CGA) should be used to compare early developmental milestones related to babbling.

A pediatrician can screen children for speech and language delays and may recommend further evaluation by a specialist, such as a speech-language pathologist. Proctor (1989) and Mitchell (1997) have provided instruments and guidelines for assessing vocal development of infants. Standardized evaluation tools, such as the *Communication and Symbolic Behavior Scales Developmental Profile* (Wetherby and Prizant 1993), and criterion-referenced assessments such as the *Rossetti Infant and Toddler Language Scale* (Rossetti 2006) can also be utilized to assess language in the pre-linguistic period.

For children who do not follow the expected progression of babbling and demonstrate a delay in speech and language development, early intervention which is specifically tailored to the individual, targets behavior and communication, and involves the parents or primary caregivers is the best treatment. Typically, a speech-language pathologist implements this intervention.

Future Directions

Many children who are later diagnosed with autism first present to their pediatrician with

delays and differences in speech and language development (Johnson 2008). Still, autism is not typically diagnosed until about 3–5 years of age. Research has shown that early intervention by 2–3 years of age results in more positive outcomes for children with autism (Osterling and Dawson 1994). Since language and communication impairments are part of the diagnostic criteria for autism, and babbling is one of the earliest developmental communication milestones which has been shown to be an important initial phase of speech production ability, lack of babbling by the end of the first year or regression of early speech skills should be recognized as a red flag. More studies on the different patterns and progressions of babbling in children with autism spectrum disorders would help professionals to better understand the link with later speech and language development and help to support earlier identification of children who may be at risk.

Caregiver training program

Definition

A training program with supplemental informational materials has been developed with strategies to support short-term care for individuals with autism spectrum disorders (ASD). This program, entitled *Sit for Autism*, was originally designed to inform babysitters by increasing their understanding of young children with ASD and how to best support their needs. However, as the training program began to be implemented, the trainers determined that birth parents, foster parents, grandparents, and other caregivers can benefit from the information presented. These diverse caregivers could then use the tools provided to assist babysitters in caring for their children with ASD. This entry includes a general description of the program and next steps for implementation.

The *Sit for Autism* 2-h training session includes delivery of factual-based information and hands-on activities. In the initial portion of the training, a PowerPoint presentation is used to share

foundational content, including the definition of ASD, strengths of children with ASD, and common social, communication, and behavior characteristics of individuals with ASD. Key theories [Theory of Mind (Baron-Cohen 1995)] and challenges exhibited in the realms of behavior and social communication are explored through content and active engagement of the participants. Along with related content about ASD, targeted evidence-based practices (EBPs) (Wong et al. 2013) are defined and modeled, and a detailed babysitter preparation packet is also provided. Suggestions for implementing the target EBPs in the home and/or community setting are discussed and applied to scenarios presented by the trainer and participants. Opportunities for the participants to reflect on their personal experiences, ask questions, share strategies, and actively engage in dialogue are available throughout the training. Each participant is given the opportunity to practice using these tools during the training session and benefit from presenter feedback.

Participants are given a “Sit Kit” containing PowerPoint with factual information and explanation, written instructions for use of each EBP strategy, Babysitter Sit Preparation guide booklet, and visual supports related to the presented EBPs (visual schedule options, choice board, communication pages, and timer options). A visual timer and instructions on its use are included in each kit.

The included “Babysitter Sit Preparation” guide booklet is to be completed by the caregiver before leaving their child as a means of sharing with the babysitter or other potential temporary caregivers ways to support and understand their child. The information presented in the guide provides the caregiver with a breakdown of the child’s skills and challenges in social, communication, and behavior and allows for personalization of strategies to utilize during the time of short-term care. Pages referred to as “The Sit Prep Kit” components provide the opportunity to share emergency contact information, medical information, food preferences, the child’s typical schedule, special equipment needed, the bedtime routine, adaptive areas in need of assistance, homework routine, activity preferences, and information about siblings and what the child

likes to do with the siblings. The final page includes a space to write down the expected schedule of activities for the time of the babysitting/temporary care event.

At the conclusion of the training, ten tips for success when providing short-term care to an individual with autism are reviewed. These include providing structure; being consistent; using visuals; providing warning time when an activity is over; giving short, clear directions; limiting verbal language; leaving time for the child to answer; being attentive; being understanding and supportive; and supporting with humility. A final question and answer session concludes the training. Trainer contact information is provided to the participants for any follow-up they would like to have with the trainer.

This Sit for Autism training has been conducted 55 times from 2013 through April 2019. A total of 526 participants from a variety of socioeconomic and ethnic backgrounds throughout the state of Connecticut attended the training. In an effort to expand access of the materials by more families, all of the materials have been translated into Spanish. Translators to support the presenters have attended several sessions, with an exclusive training session in Spanish piloted. “Sit Kits” are offered to participants in electronic format so that parents and caregivers can personalize them and use them on more than one occasion. A Train the Trainer model has been developed to begin to train other professionals in order to reach more families in the state.

Balovaptan

Zachary J. Williams^{1,2} and James C. McPartland³

Definition

Balovaptan (previously RG7314) is an investigational drug candidate developed by Hoffman-La Roche for the potential treatment of autism spectrum disorder (ASD). It is an orally active non-peptide vasopressin receptor antagonist (vaptan) with reported selectivity for the vasopressin V1a receptor. Balovaptan is the first vaptan drug to be tested in psychiatry, and its therapeutic potential is yet unknown. Based on the results of a recent phase II clinical trial in adults with ASD (Bolognani et al. 2017), balovaptan was granted “breakthrough therapy” designation by the United States Food and Drug Administration in January

2018. The drug is currently undergoing a phase II clinical trial in children and adolescents with ASD for the alleviation of core ASD symptoms. To date, data on the safety or efficacy of balovaptan have not been published.

Vasopressin, also known as antidiuretic hormone, is a small peptide produced in the hypothalamus. It is a major physiological regulator of water homeostasis, affecting urine concentration and blood volume. Vasopressin binds to three different receptors, V1a, V1b (also called V3), and V2. Activation of V1a receptors on vascular smooth muscle causes vasoconstriction, and activation of V2 receptors promotes water reabsorption in the kidneys. V1a receptors are also expressed on neurons throughout the central nervous system, and vasopressin is known to act as a neuromodulator. The physiological effects of the V1b receptor are less well characterized, though V1b activation is thought to promote the release of adrenocorticotrophic hormone (see ► [“Hypothalamic-Pituitary-Adrenal Axis”](#)). The study of vaptan drugs has primarily focused on agents that antagonize renal V2 receptors (e.g., conivaptan, tolvaptan) and their ability to treat conditions characterized by hyponatremia and fluid overload (Ali et al. 2007). However, a single-dose proof-of-mechanism study testing a small-molecule V1a antagonist (RG7713) in adults with ASD has provided preliminary evidence that targeting this receptor improves social cognition (Umbricht et al. 2017). Thus, in addition to promoting diuresis, vaptan drugs are potentially useful as therapeutics for neuropsychiatric disorders.

Though there is limited evidence supporting vasopressin system dysfunction in the pathogenesis of ASD, both vasopressin and the related neuropeptide oxytocin (see ► [“Oxytocin”](#)) have been implicated in the regulation of social cognition and behavior (Meyer-Lindenberg et al. 2011). Oxytocin and vasopressin interact with a number of other neurotransmitter systems, and the mechanisms by which they alter social functioning in humans have yet to be fully understood. Nevertheless, the oxytocin and vasopressin systems remain feasible targets for novel therapeutics that aim to address the social-communicative

symptoms of ASD (Baribeau and Anagnostou 2015). A phase I clinical trial of balovaptan was completed in 2015, testing the drug in healthy adults between 18 and 45 years of age. The phase I trial attempted to replicate previously reported effects of vasopressin administration on brain activity and functional connectivity during functional MRI tasks. Notably, this trial only included males, as the effects of oxytocin and vasopressin are thought to differ by sex. To establish proof of mechanism, the study assessed the ability of balovaptan to modulate vasopressin-induced changes in brain activity. The results of the trial were not published, though the drug has continued to the next stage of testing.

The most recent data on balovaptan's effects come from the VANILLA (Vasopressin ANtagonist to Improve social communication in Autism) study, a phase II clinical trial in adult males with ASD and normal intellectual functioning, primarily investigating the compound's safety and efficacy in this population. Results of this study were presented at the 2017 International Meeting for Autism Research (Bolognani et al. 2017). A total of 223 patients were randomized to either the placebo condition or 1 of 3 dosages (1.5 mg, 4 mg, 10 mg) for 12 weeks, and of those individuals, 192 (86%) completed the trial. Although the drug appeared to be safe and well-tolerated over the treatment period, there was no change in the primary endpoint (caregiver reported Social Responsiveness Scale Scores) between drug and placebo groups. However, at the 4 and 10 mg doses, significant differences emerged between drug and placebo on the Vineland Adaptive Behavior Scales (VABS), one of the secondary endpoints. Between baseline and the 12-week endpoint, VABS composite scores improved over placebo with effect sizes of 0.59 in the 4 mg group and 0.49 in the 10 mg group. Further analyses of this effect found the improvement in composite scores to be driven by the social and communication domains of the VABS. No consistent treatment effects were noted in any of the other secondary endpoints, including the Aberrant Behavior Checklist (ABC); the Repetitive Behavior Scale-Revised (RBS-R); the State-Trait Anxiety Inventory (STAI); the Anxiety, Depression, and Mood Scale (ADAMS); and the

CGI-I score. While the primary endpoint was not significant in this trial, the compound's effect on VABS scores has caused the drug maker to alter its methods for future investigations. Currently, a second phase II trial of balovaptan (aV1ation; NCT02901431) is under way in children and adolescents with ASD, this time utilizing the VABS as the primary endpoint.

Barnes Akathisia Scale

Wouter Staal
Neuroscience, Radboud University Nijmegen
Medical Centre Karakter, Nijmegen,
The Netherlands

Definition

The Barnes Akathisia Scale is a scale designed to rate the severity of drug-induced or Parkinson disease-based akathisia. Akathisia – literally meaning not sitting – is characterized by an inner restlessness, causing constant motion of hands or feet. Symptoms of akathisia can persist for years, even after discontinuing the precipitating drug. The assessment of akathisia with the Barnes Akathisia Scale includes objective and subjective questions.

Barriers and Facilitators that Prevent and Enable Physical Healthcare Services Access for Autistic Adults

David Mason¹, Barry Ingham² and Jeremy Parr^{1,3}

¹Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, UK

²Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle, UK

³Sir James Spence Institute, Institute of Health and Society, Newcastle University, Royal Victoria Infirmary, Newcastle Upon Tyne, UK

Definition

A barrier to physical healthcare access is any component of healthcare provision that negatively impacts the healthcare service access of autistic people. Conversely, facilitators are components of healthcare provision that improve the healthcare service access of autistic people. Barriers that affect the physical healthcare access of autistic people include communication, health professional's knowledge about autism, sensory sensitivities, and cognitive factors (Mason et al. 2019). Brief information is given below about these factors, with examples; more information is contained in the referenced papers.

Autistic people's communication style (e.g., difficulty describing symptoms, particularly those that involve abstract concepts or hyper-specific language) can be a barrier to healthcare provision (Nicolaidis et al. 2015). Moreover, some autistic people may not provide key information unless questions directly ask for this information (Bradshaw et al. 2019). But it is important to be mindful that communication

involves two parties, so a clinician's responsiveness (or lack thereof) to alternative communication styles (e.g., written notes) can act as a facilitator (or barrier) to healthcare provision (Mason et al. 2019).

Autistic people report that some clinicians have limited knowledge about autism. This can lead to clinicians making assumptions about the capabilities of autistic people (e.g., that the autistic person is not fully competent if they attend an appointment with a friend/family member) or clinicians assuming that behavioral expressions of symptoms (e.g., pain) are a part of autism (Nicolaidis et al. 2015). This agrees with many studies which have also identified that clinicians report a lack of knowledge about, but desire to learn more about, autism (Morris et al. 2019). (Note, some data indicate that many clinicians do know the key features of autism; Unigwe et al. 2017.)

Sensory sensitivities can affect multiple aspects of a healthcare visit: travel to a visit, waiting rooms, and during the visit itself. Autistic people can experience sensory issues when using busy or noisy public transport (Bradshaw et al. 2019). Waiting rooms can be problematic for autistic people due to lighting (e.g., bright fluorescent light) or being crowded; this may mean autistic people avoid seeking appointments if this environment cannot be avoided. Likewise, lighting during a healthcare visit may be too bright, or the walk from the waiting room to the healthcare provider's office may be disorientating.

The cognitive factors unique to each autistic person can also be a barrier to healthcare access. Due to the cognitive load of managing social presentation, or trying to process verbal information in "real time," autistic people find it difficult to understand information from health professionals (Mason et al. 2019; Raymaker et al. 2017). Moreover, prospective memory difficulties (e.g., accurately recording future appointments or remembering to take medication) can be a barrier. Therefore, autistic people may need more support in how healthcare information is disseminated (e.g., audio recordings of appointments or a clearly phrased written summary of the appointment) (Mason et al. 2019).

These barriers can interact. For instance, the anxiety brought about by being in a waiting room has a consequence for the subsequent healthcare appointment. An autistic person who is anxious (or exhausted from attempting to manage typical healthcare settings) may then find interacting with the healthcare provider more difficult or may find processing healthcare information, or providing information about their needs, more challenging. This means more time in the appointment will be spent on maintaining the conversation and coping with anxiety, with less time spent processing the content of the healthcare discussion. Thus, the autistic person may leave without sufficient knowledge about the discussion or with multiple questions that were not addressed in the appointment.

Barriers to and Facilitators of Successful Early School Transitions for Children with Autism Spectrum Disorders

Laura Fontil¹, Emily Beaudoin², Jalisa Gittens² and Ingrid E. Sladeczek²

¹Department of Educational and Counselling Psychology, School/Applied Child Psychology, McGill University, Montreal, QC, Canada

Synonyms

[Early school beginnings](#); [Successful school transition](#); [Transition support practices](#)

Definition

The shift from an early childhood setting (e.g., home, preschool) to elementary school can be challenging for children, their families, and their teachers. Families must adapt to important changes once children transition to school (TTS), such as increased academic and social demands, decreased family support, and more transitions throughout the school day (Rimm-Kaufman et al. 2000). This shift tends to be particularly challenging for children with neurodevelopmental disorders, such as autism spectrum disorder (ASD). In addition to the challenges experienced by neurotypical children, the social/communication deficits and challenges adapting to change experienced by children with ASDs make the transition to a novel, social environment like school particularly problematic for children with ASDs and their families (Forest et al. 2004).

Research suggests that the implementation of collaborative transition practices can facilitate the TTS for children with ASDs and their families (Fontil et al. 2019a, b). Transition support practices can be defined as a series of activities that are implemented before, during, and/or after the TTS to support the child and family as they move from one educational environment to the next. Examples of transition support practices include transition planning meetings, school visits, and school orientations. The implementation of high-quality TTS supports (i.e., supports that are individualized to the child and their family's needs and involves direct contact with families) has been correlated with positive social and academic outcomes for children.

Collaboration between key stakeholders in a child's life is essential to facilitating successful school beginnings. That is, home, the sending school (e.g., preschool, intervention center, day care), and the receiving school should be in communication (e.g., transition meetings, sharing information concerning the child between early childhood settings and schools) and aim to develop meaningful partnerships characterized by open communication, valuing insights provided by family members, and considering the needs and values of families. Parents of children with ASDs have reported experiencing more stress than parents of children with other developmental disabilities (DDs; Griffith et al. 2010), which could be attributed to distinct characteristics that are associated with ASDs (i.e., delayed diagnosis, more behavioral problems, lack of reciprocity; Griffith et al. 2010). Furthermore, a common theme in the literature among parents of children with ASDs is a lack of collaboration between home and school during the transition planning (Fontil et al. 2019b). Given that the TTS is often especially stressful for families with children with ASDs, mutual respect and meaningful partnerships need to be underscored and made a priority.

Although collaboration is integral in facilitating successful school beginnings, several other important transition support practices have been highlighted in the literature for children with and without DDs. Child classroom visits, teacher home visits, and caregiver orientation services

are significant predictors of academic achievement (Schulting et al. 2005). Furthermore, increasing the number of school visits (i.e., 5–7 visits), prior to the TTS, is more valuable than having the child visit the receiving school a few times (Schischka et al. 2012), and implementing a greater variety of transition practices is correlated with improved academic outcomes (Ahtola et al. 2011). Early intervention program staff, servicing children with ASDs, report using a diverse set of transition supports to facilitate elementary school entry. For example, program staff provide receiving schools with information concerning a child, discuss the TTS with families, meet staff at the receiving school, encourage families to visit and meet staff at the receiving school, and hold transition planning meetings (Fontil et al. 2019a).

Despite the social and academic implications of implementing high-quality transition supports, several barriers impede the implementation of collaborative transition practices. Commonly cited barriers to collaborative transition support practices for families with children with ASDs include lack of time, lack of resources, insufficient school staff training, and divergent beliefs concerning the transition planning process (Fontil et al. 2019b). Furthermore, families of children with ASDs report being unsatisfied with receiving school support, lack of continuity of care between sending and receiving programs, and a lack of collaboration between home and the receiving school (Fontil et al. 2019b).

The extant literature on TTS has highlighted that there are more commonalities than differences when we compare transition experiences of children with ASDs to those of children with other DDs, with the exception that children with ASD have more difficulty with horizontal transitions (i.e., smaller transitions throughout the day; e.g., moving from classroom to playground). These smaller, daily transitions are more common in elementary schools in comparison to the preschool environment (Fontil et al. 2019b). Additionally, elementary school staff report exhibiting an insufficient amount of ASD-specific knowledge, which may have an impact on their capacity to successfully integrate students (Fontil et al. 2019b). Similarly, global comparisons, between

countries, reveal an international shift in attention toward TTS policy and practices which are supported by the growing number of TTS studies over time (Fontil et al. 2019b).

Based on the literature, systemic changes are needed to promote better TTS for children with ASD. Provided with sufficient financial support, school teachers could be provided with resources to develop their knowledge to facilitate transition practices (i.e., workshops and training on individuals with diverse needs, release time to visit children's sending programs). Additionally, families and caregivers need to be supported throughout the transition process (i.e., providing information about school supports). Finally, transition support practices require involvement of all key stakeholders to facilitate collaborative transition practices; this includes active engagement between families, teachers, and other professionals (i.e., occupational therapists or resource teachers).

Future research should focus on evaluating the effectiveness of specific TTS supports for students with ASD. Current research investigating transition supports tend to be descriptive in nature. Future research should investigate efficacy through randomized control trials. Furthermore, it is important to more clearly differentiate the needs of children with ASDs from those with other DDs at the point of school entry to facilitate a clearer understanding of the specific supports that facilitate TTS for children with ASD.

Barriers to Formal Diagnosis of Autism Spectrum Disorder in Adults

Laura Foran Lewis

College of Nursing and Health Sciences,
University of Vermont, Burlington, VT, USA

Definition

Factors that complicate the process of receiving a medical diagnosis of “autism spectrum disorder” by a qualified professional for autistic adults who were not diagnosed in childhood.

Historical Background

Known prevalence of autism in adults is approximately 1.1%, but this is likely underestimated (Brugha et al. 2016). Experts estimate that as many as 40% of autistics are not diagnosed in childhood (Baron-Cohen et al. 2009). Those at highest risk of being misdiagnosed or not recognized during childhood include females, middle-aged and older adults, and individuals with more subtle traits and without cognitive or language delays.

In general, females are at a disproportionate risk of misdiagnosis, delayed diagnosis, and not receiving a diagnosis compared to males across age groups (Loomes et al. 2017). There are many theories on the causes of missed diagnosis of autism among females. Emerging evidence shows a slightly different clinical presentation of autism among females, often referred to as the female autism phenotype, which might be missed by clinicians, parents, teachers, and others looking for “classic” traits more common in males. Females may be more likely to exhibit subtle and internalized symptoms and less likely to show overt restricted interests than males (Bargiela et al. 2016; Loomes et al. 2017). “Camouflaging” is also common among females, in which individuals learn strategies to mask autistic traits and model typical social behaviors, making it more difficult to detect a diagnosis. Little is known about the impact of gender bias on diagnosing individuals who identify with a gender other than sex assigned at birth (e.g., agender, non-binary, genderqueer, transgender), but it is likely that these individuals are also at increased risk of missed diagnosis due to a reliance on male norms for the development of current diagnostic tools.

Middle-aged and older adults are also at risk of missed diagnosis due to lack of awareness and understanding of autism during their childhood, particularly since the categorization of autism in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) has changed significantly over time. Autism did not appear in the DSM until 1980, and prior to the release of the DSM-III-R in 1987, diagnostic criteria for autism limited this

label to individuals with severe symptoms and onset by age 30 months. The DSM-IV, released in 1994, was the first edition to identify autism as a “spectrum” and included the category of Asperger’s disorder for the first time, which could include individuals with more subtle traits. Many adults who grew up prior to these changes in the DSM were not diagnosed with autism because the criteria had not yet been established.

In the most recent edition, the DSM-5 eliminated the term “Asperger’s” and categorized autism as a continuous spectrum called “autism spectrum disorders.” The latest categorization identifies traits that may appear across the lifespan and does not identify a specific window of onset, which may increase clinician’s ability to apply this diagnosis to adults meeting the criteria. However, there is growing evidence that the latest criteria are more likely than the previous categorization to exclude females, older individuals, individuals with above average intelligence, and individuals with subtle traits (Mazurek et al. 2017).

Adults are increasingly becoming aware of their own autistic identity with a rise in media representation of autism, biographical accounts of diagnosis during adulthood, and online presence of support groups and forums related to autism. In addition, many adults recognize their own autistic traits when their children are diagnosed with autism. Self-diagnosis of autism is a growing phenomenon, and many individuals report they are satisfied with a self-diagnosis and confident in their autistic identity without seeking a formal diagnosis (Lewis 2016a). However, others who are self-diagnosed report recurring self-doubt about their autism status and experience unresolved cyclical grief. Without a formal diagnosis, individuals are also ineligible for professional support of any kind and typically lack access to community resources.

There are known benefits to obtaining a diagnosis beyond increased access to services. Individuals who are formally diagnosed report that awareness of their autistic identity was often a relief and led to a new sense of belonging, empowerment, understanding of strategies to improve quality of life, and increased self-acceptance (Crane et al. 2018; Lewis 2016b).

Many autistics are unaware of their diagnosis until adulthood, and awareness of autism can significantly benefit their mental health.

Current Knowledge

Autistic adults seeking diagnosis face significant barriers, and 80% report that obtaining a formal diagnosis was difficult or not possible (Taylor and Marrable 2011). The process of obtaining a formal diagnosis typically takes years, and on average adults see five professionals before receiving a diagnosis (Jones et al. 2014; McKenzie et al. 2015).

Barriers identified by adults seeking formal diagnosis include anxiety; cost; lack of access to adult specialists and limited awareness of autism by most professionals; inability to describe their symptoms; fear of not being believed or understood; lack of rapport or mistrust of healthcare professionals; stigma; and complexity of the healthcare system (Crane et al. 2018; Lewis 2017; Taylor and Marrable 2011; Vogan et al. 2017).

Characteristics of autism can exacerbate these barriers, creating a gap that precludes diagnosis for those with challenges not severe enough to be detected in childhood but too severe to pursue a diagnosis in adulthood. For example, deficits in social functioning often lead to social anxiety, which may prevent individuals from making an appointment with a healthcare professional due to worries about social interactions with receptionists, clinicians, etc. Individuals may also feel anxiety about the sensory experience of the waiting room or office that prevents them from making an appointment or following up.

In addition, approximately half of autistics experience alexithymia, or difficulty identifying and verbalizing their own feelings and emotions, which may make it difficult for them to communicate their symptoms adequately to a professional who does not specialize in autism (Trammell et al. 2013). They may also struggle with introspection or be unable to recognize their own autistic traits.

Individuals who have challenges with executive functioning, which includes tasks such

as organizing, focusing, and multitasking, may have difficulty navigating the healthcare system, planning for transportation, keeping appointments, or coordinating other tasks needed to pursue a diagnosis. Many individuals seeking a diagnosis of autism are also unemployed or employed part time (Happé et al. 2016), which may prohibit them from being able to maintain insurance or to afford the costs associated with evaluation and diagnosis.

Fear of not being believed, being dismissed by clinicians, or being blamed for symptoms is very common among adults seeking diagnosis, particularly among females (Crane et al. 2018; Lewis 2017). Adults report that they feel they are at the mercy of their clinicians for referrals as gatekeepers of diagnosis and fear that lack of clinician awareness of autism presentation in adults or in females may prevent them from receiving a diagnosis. Many fear detrimental effects on their identity formation if they are evaluated and told they do not meet criteria for a diagnosis of autism. Individuals who believe they are autistic also commonly report that they feel they have been misdiagnosed with co-occurring mental health conditions due to a lack of clinician understanding of their autistic traits, for example, that autistic traits are confused with another diagnosis or that difficulties with mental health are indirectly caused by autism (Au-Yeung et al. 2018).

Beyond those barriers identified by autistics, clinicians also cite significant barriers to making a diagnosis of autism in adults. Since autism is a neurodevelopmental condition, it is characterized by the presence of autistic traits in the developmental period. One significant barrier to clinicians making a diagnosis is the practicality of interviewing a parent or other reliable individual who can speak to the presence of these traits during childhood (Lai and Baron-Cohen 2015; Trammell et al. 2013). There may be limitations such as the willingness or availability of informants to meet, their ability to recall details from the individual's early childhood, or their perception of key events compared to the individual seeking a diagnosis (e.g., what they view as culturally "typical" vs. "atypical" behavior). If a parent or childhood caregiver cannot provide this information,

clinicians may opt to meet with other informants who can speak to the individual's childhood such as an older sibling or other relatives. If no such informants are available, clinicians must rely on educational and medical records and the adult's recollection of childhood for information on the developmental period, which may lack sufficient detail to make a diagnosis.

Clinician knowledge of autism is another significant barrier to adult diagnosis. Few instruments exist to assist in the assessment of adults, and even fewer have validated norms for adults. While the Autism Diagnostic Observation Schedule (ADOS) module 4 is the only validated tool for adult diagnosis, this must be used with caution due to its limited sensitivity to detect symptoms in females and individuals who have learned strategies that may camouflage symptoms (Lai and Baron-Cohen 2015; Trammell et al. 2013). Adult diagnosis of autism relies heavily on clinician expertise, and few clinicians specialize in evaluating adults for autism. Primary care providers report limited understanding and lack of training about autism in general, with three out of four clinicians rating their knowledge and skills in providing care to autistic patients as poor or fair (Zerbo et al. 2015).

Diagnosis is further complicated because more than 70% of autistics have at least one co-occurring medical, psychiatric, or developmental condition, most often including anxiety and mood disorders (Happé et al. 2016; Lai and Baron-Cohen 2015; Trammell et al. 2013). Since many differential diagnoses have overlapping symptoms or traits, clinicians may struggle to determine whether characteristics are related to autism, a co-occurring condition, or a differential diagnosis. Making a differential diagnosis is especially challenging when clinicians are missing key information about onset of traits and the developmental period.

Person-environment fit and cultural norms can also significantly impact interpretation of behaviors and traits and prevent diagnosis (Lai and Baron-Cohen 2015). That is, what is considered typical social behavior in one environment may be considered atypical in another environment. Therefore, an individual with many autistic traits

but whose traits do not interfere with functioning might not meet criteria for diagnosis, while an individual with fewer autistic traits that do interfere with functioning might meet criteria for diagnosis. These nuances may complicate the process of determining a diagnosis in adulthood where developmental milestones are more ambiguous.

Given these factors, even if the autistic individual is able to overcome the significant barriers that may prevent them from meeting with a clinician and accurately communicating information about their autistic traits, clinicians still might not be able to make an accurate diagnosis. For those who actually receive a diagnosis, experiences are often negative, with 40% of autistics reporting they were "very/quite dissatisfied" with the diagnostic process (Jones et al. 2014).

Future Directions

Given the potential benefits of recognizing autism for identity building and self-acceptance, it is critical to increase access to diagnosis for those on the spectrum. The World Health Organization recommends screening all children for autism as part of routine care (World Health Organization 2018), and over time, this practice should help reduce the number of adults who were not diagnosed in childhood.

There continues to be a paucity of validated tools for screening and diagnosis of autism in adults, which is a research priority (Wigham et al. 2018). Increased attention must be paid to developing diagnostic tools for all ages that recognize subtle and internalized traits that are more likely to be seen in females and individuals without cognitive impairment or language delays.

Clinicians across practice settings also require increased training on autism. Primary care providers may be the only healthcare professionals in position to detect autism in undiagnosed adults, so knowledge of common presentation is critical. There is a need for increased education in undergraduate and graduate settings for healthcare professionals to increase identification of autism and to minimize the negative experiences of those

who feel that their autistic characteristics are dismissed by clinicians who lack understanding of adult presentation (Zerbo et al. 2015).

All professionals must also be mindful of the significance of self-diagnosis in adults who believe they are autistic. Since such significant barriers to diagnosis exist, many adults rely on a self-diagnosis for autistic identity formation (Lewis 2016a). Dismissal of a self-diagnosis by a professional may be detrimental to self-acceptance and understanding. Professionals must be mindful of their own preconceptions about self-diagnosis and remain open to exploring the potential of an autism diagnosis in those who perceive themselves as being on the autism spectrum even if “classic” autistic traits are absent.

For those who do receive an autism diagnosis in adulthood, little to no post-diagnostic support is offered. Most individuals indicate that they would like counseling, social skills training, and access to support groups. However, as many as 77% receive no support whatsoever after diagnosis (Jones et al. 2014; Taylor and Marrable 2011), and qualitative studies indicate that individuals often feel lost and directionless and lack support after diagnosis (Crane et al. 2018; Lewis 2016b). There is a need for an effective and evidence-based approach to assist adults in managing mental health challenges as well as providing practical supports and resources after diagnosis.

Though formal services are limited, there are several online communities that promote positive images of autism and neurodiversity. Many adults utilize these websites to seek information and connection while working through the diagnostic process and beyond. Table 1 provides examples of some of these sites.

There are many severe barriers to formal diagnosis of autism in adulthood. Primary barriers include autistic traits themselves that prevent the individual from obtaining an assessment, lack of understanding of adult presentation of autism by clinicians, the impracticality of including informants from the developmental period in assessment, and the lack of appropriate tools for adult diagnosis. Given the potential mental health benefits of being aware of autism identity, researchers

Basal Ganglia

Youngsun T. Cho

Yale Child Study Center, New Haven, CT, USA

Synonyms

Striatum; Sub-cortical ganglia

Definition

“Basal Ganglia” refers to a collection of sub-cortically (beneath the cortex) located nuclei in

the brain. Originally, these nuclei were collectively identified as a conduit for information to pass from cortical association regions to motor cortex for the initiation and control of movement. Today, the function of the basal ganglia is thought to include not only the shaping of motor responses, but also the integration of emotional, motivational, and cognitive information. The integration of such a wealth of information has been shown to contribute to motivated behaviors, habit formation, and motor learning. As part of these functions, the basal ganglia provides a locus of control for movement – simultaneously suppressing unwanted movement and enhancing desired movement (Mink 1996).

The subcortical structures typically included as part of the basal ganglia are: caudate nucleus and putamen (collectively called the striatum), nucleus accumbens (included in the ventral striatum), globus pallidus (both internal (GPi) and external (GPe) segments), substantia nigra (both pars compacta (SNpc) and pars reticulata (SNpr)), and the subthalamic nucleus (Groenewegen 2003). The interconnections between the nuclei of the basal ganglia allow for this collection of regions to act as a unit (Fig. 1). Together, they allow the impulses for movement and other behaviors that originate in the cortex to be refined towards a final output and expression.

The main input region of the basal ganglia is considered to be the striatum. The striatum receives cortical information that is topographically distributed based on the type of information. Emotional, associative, cognitive, and motor information from the cortex uniquely arrive in specific regions of the striatum, distributed in a ventral (bottom) to dorsal (top) manner, respectively. Information from the striatum then splits into two main pathways. The “direct” pathway channels information from the striatum to either the substantia nigra or the globus pallidus interna, the two major output regions of the basal ganglia. From these regions, information is then sent to the thalamus; the thalamus sends this, now processed, information back to the cortex. By contrast, the “indirect” pathway passes information first from the striatum to the globus pallidus externa and subthalamic nucleus, and then to the globus pallidus interna and substantia nigra

Basal Ganglia, Fig. 1 Schematic of the direct and indirect pathways of the basal ganglia. SNpc,pr, Substantia Nigra, pars compacta and pars reticulata; GPe, Globus pallidus external segment; GPi, Globus pallidus internal segment; STN, Subthalamic nucleus

for output to the thalamus. As with the direct pathway, the information sent to the thalamus is directed back to the cortex. The indirect and direct paths have distinct neurotransmitters and receptor profiles, and together form the “cortico-basal-ganglia-thalamo-cortical loops” that contain distributed emotional, motivational, associative, cognitive, and motor information (Alexander et al. 1986). These loops allow the impulses that originate in the cortex to be refined through the basal ganglia, and then sent back to cortex for a motor response output.

Abnormalities in the basal ganglia have been proposed to account for some of the symptoms of autism, including repetitive motor behaviors, decreased social interest/ability, and general motor dysfunction. The caudate nucleus, in particular, has been shown to have accelerated growth in children with autism, compared to typically developing children (Langen et al. 2014). This fits with other studies demonstrating an enlarged striatum in patients with autism. In animal models of autism, abnormalities in striatal interneurons, the small, local neurons that are key for regulating the neurons in the

striatum that project to other regions, are thought to underlie striatal pathology. Decreased anticipation and processing of social rewards, and rewards in general, along with decreased recruitment of the ventral striatum have been noted, identifying a potential mechanism for decreased sociability in autism. Given these striatal abnormalities, the question of whether motor abnormalities are primary, and the resulting symptoms of autism are merely secondary to those motor abnormalities, has been raised (Subramanian et al. 2017). Further research is needed to test this and to better understand the specific basal ganglia abnormalities in autism.

BASC-2

- Behavior Assessment System for Children, 2nd Edition

BASC-3

- BASC-III

BASC-III

Kimberly Ho Misiasek

Yale Child Study Center, New Haven, CT, USA

Synonyms

- BASC-3

Description

The Behavior Assessment System for Children, Third Edition (BASC-3) is a multimethod, multi-dimensional system that provides a comprehensive assessment of behavioral and emotional functioning in children, adolescents, and young adults from ages 2 to 25 (Reynolds and Kamphaus 2015). Its multiple components (hence multimethod) can be used individually or in combination and include: The Behavioral and Emotional Screening System (BESS), Teacher Rating Scales (TRS), Parent Rating Scales (PRS), Self-Report of Personality (SRP), Structured Developmental History (SDH), Student Observation System (SOS), Behavior Intervention Guide, Behavioral and Emotional Skill Building Guide, Flex Monitor, and Parenting Relationship Questionnaire (PRQ™). Used together, the information yielded from the components aid in clinical diagnosis and identifying educational supports and services (Reynolds and Kamphaus 2015). Emotional and behavioral functioning specific to a certain setting or context is provided when used individually. Additionally, the BASC-3 assesses positive and negative aspects of personality and behavior, making it multidimensional in nature (Altmann et al. 2018).

A detailed review of each component is provided in the manual (Reynolds and Kamphaus 2015) thus only a brief description of each follows:

- The TRS and PRS each have three age level forms (preschool, child, and adolescent) and measure adaptive and problem behavior in the school and home setting using a four-point Likert scale ranging from *Never* to *Almost Always*.
- The SRP captures respondents' feelings, behaviors, and self-perceptions and has forms for children, adolescents, and young adults (Reynolds and Kamphaus 2015).
- The SDH captures developmental information across a variety of domains that can aid in diagnosis and treatment.
- The SOS allows for a 15-min period of a student's behavior in a classroom to be recorded and evaluated.

The following descriptions are on the BASC-3 components that identify, monitor, and promote optimal behavioral and emotional functioning:

- The BESS is a quick screener that identifies behavioral and emotional problems in children and adolescents and can be filled out by teachers, parents, and students ages 8–18.
- The Behavior Intervention Guide is a compilation of evidence-based strategies for common emotional and behavioral problems that can be applied by a variety of behavioral professionals (Altmann et al. 2018).
- The Behavioral and Emotional Skill Building Guide provides small-group activities that promote and enhance positive behavioral and emotional skills (Reynolds and Kamphaus 2015).
- The Flex Monitor is an Internet-based tool that allows professionals to monitor and track a customizable set of emotions or behaviors which can be compared to a nationally representative population sample, in order to measure behavioral change over a period of time (Reynolds and Kamphaus 2015).
- The PRQ captures the parent's perceived relationship between themselves and the child, and

assesses dimensions such as attachment, involvement, parenting style, stress, and school satisfaction (Reynolds and Kamphaus 2015).

Historical Background

In 1992, after seven years of development, standardization, and validation, the Behavior Assessment System for Children (BASC) was published due to the need for a psychometrically sound and integrated assessment of child and adolescent emotions and behaviors, appropriate for multiple settings (Reynolds and Kamphaus 2015). In 2004, the BASC-2 was released and quickly became the most commonly used set of behavior rating scales in public schools in the USA and internationally (Reynolds and Kamphaus 2015). In 2015, the third edition was published, with the addition of electronic administration and scoring, improved interpretive reporting, and Flex Monitor (see above in “[Description](#)” section) (Reynolds and Kamphaus 2015).

Psychometric Data

The TRS, PRS, and SRP were designed based on a combination of theory and empirical data. Over 120 teachers, 100 parents, and 400 students were surveyed about negative and positive behaviors observed in home and classroom settings (Reynolds and Kamphaus 2015). Approximately 90 negative and 50 positive behaviors were identified and compared to the BASC-2 item pool, and around 10–15 new items were written for the BASC-3 TRS, PSR, and SRP standardization forms (Reynolds and Kamphaus 2015). To ensure each domain had content that was adequate and relevant, a review of the BASC-2 forms, the newly written items, and items on the original BASC served as the basis of the standardized form items (Reynolds and Kamphaus 2015). General norms were derived from data collected from a large and representative sample of children across the United States, while children with a diagnosis of one or more emotional or behavioral problems ages 4 through 18 comprised the clinical norms sample (Reynolds and Kamphaus 2015).

The BASC-3 Manual provides evidence of reliability by reporting internal consistency, test-retest reliability, and interrater reliability for the TRS, PRS, and SRP (Reynolds and Kamphaus 2015). Overall, the scales and composites were found to have reliability coefficients of 0.80 and above, thus demonstrating the ability to reliably estimate behavior for diagnostic and treatment planning. Extensive validity evidence is also provided in the BASC-3 Manual for each scale including scale intercorrelations and factor analyses, correlations with other rating scales, and score profiles of groups of children with particular clinical diagnoses or educational classifications (Reynolds and Kamphaus 2015). Additionally, the BASC-3 contains validity indices that allow for the detection of untruthful responding, carelessness, extreme responding, or other validity threats (Reynolds and Kamphaus 2015).

Clinical Uses

The BASC-3 and its components (TRS, PRS, SRP, SDH, and SOS) can be used in a variety of settings and thus has wide applications including aiding in clinical diagnosis, educational classification, manifestation determination, assessment of individuals with limitations of vision and hearing, program evaluation, forensic evaluation, and research (Reynolds and Kamphaus 2015). In regards to clinical diagnosis, the BASC-3 assesses symptoms found in the DSM-5 for disorders in childhood or adolescence. The rating scales are also sensitive to a variety of classroom problems, which help differentiate academic difficulties from behavioral problems. They also help assess severe emotional disturbance as called for by IDEA (2004) (Reynolds and Kamphaus 2015). The BASC-3 is effective in determining the origins of behavior and can be used by experienced individuals to evaluate children with sensory impairments (Reynolds and Kamphaus 2015). Lastly, the BASC-3 has been found to be helpful in the evaluation of children's progress in programs and/or their response to interventions when administered over multiple

time points, as well as in legal or forensic settings given its psychometric properties and ability to detect dissimulation (Reynolds and Kamphaus 2015).

Baseline

Cate Kraper

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

An assessment of abilities that serves as an anchor for monitoring subsequent change over time when combined with follow-up assessments. A baseline assessment may occur prior to a child entering school, or, if a child is enrolled in an intervention study, prior to administering the treatment. A baseline assessment may involve more than one assessment point, to determine the stability of a behavior prior to introducing an experimental manipulation (e.g., an intervention designed to change the behavior assessed during the baseline period). Later assessments can be compared to the baseline assessment, so that symptoms or abilities may be tracked over time, and improvements or deterioration in abilities may be noted. This may

be especially helpful for developmental disorders such as autism, in which the symptoms and their severity can change dramatically over time. In cases in which deterioration of skills occurs, the combination of a thorough baseline assessment and appropriate follow-up assessments can help identify specific skills that can be targeted in treatment. Baseline assessments might include measures of language and communication, social skills, self-help skills, play, and IQ.

Bayley Scales of Infants Development-II

Amanda Steiner
Yale Child Study Center, New Haven, CT, USA

Synonyms

[Bayley-III](#)

Description

The Bayley-III is a standardized developmental assessment that evaluates the functioning of infants and young children from 1 month to

42 months of age. It is designed to identify children with developmental delays and aid in intervention planning. The test assesses multiple developmental domains, including cognitive, language (both receptive and expressive), motor (both fine and gross), as well as social emotional and adaptive behavior. The cognitive, language, and motor scales are based primarily on direct assessment, whereas the social-emotional and adaptive behavior scales are caregiver questionnaires. Scaled scores are provided for each subtest, with composite scores and percentile ranks for each overall scale. Developmental age equivalents are also provided for cognitive, language, and motor subtests. Growth scores can also be calculated to evaluate a child's growth over time for cognitive, language, and motor subtests.

Historical Background

The Bayley Scales of Infant Development (BSID) were first published in 1969, with revisions in 1993 (BSID-II) and 2006 (Bayley-III). In its most recent edition, the test was updated to reflect updates in the field of child development research, including information processing and preverbal intelligence. However, the Bayley-III still retains its focus on more classic themes in child development (e.g., Piaget, Vygotsky). Additionally, many items from the BSID-II were removed or changed and new items were developed.

Psychometric Data

Normative data for the cognitive, language, and motor scales was collected from 1700 children aged 1 month to 42 months (with 100 individuals in 17 separate age groups) and closely reflected the 2000 US Census in terms of parental education level, race/ethnicity, and geographic region. Only children born between 36 and 42 weeks were included. Children with mental, physical, or behavioral difficulties constituted about 10% of the total sample. The social-emotional scale was normed using 456 children, and the adaptive behavior scale included 1350 children.

Clinical Uses

The Bayley-III is designed to be used to identify children with developmental delays. It is recommended that the Bayley-III be administered by an individual with formal graduate or professional training in developmental assessment. While it is possible for a psychometrician to administer the Bayley-III, test interpretation should occur by an individual with appropriate training to interpret test data.

Beate Hermelin

Uta Frith
Division of Biosciences, Institute of Cognitive Neuroscience UCL, London, UK

Name and Degrees

Beate Hermelin, BA, PhD

Major Appointments (Institution, Location, Dates)

Medical Research Council, London, ca 1960–ca 1985.

Major Honors and Awards

Queen Elizabeth II Silver Jubilee Medal

Landmark Clinical, Scientific, and Professional Contributions

Beate Hermelin was a strikingly original experimental psychologist with an unconventional career and unconventional thinking. It is impossible to talk of her work without also talking of the work of Neil O'Connor, as almost all her publications include both names. Hermelin and O'Connor conducted a series of groundbreaking

experimental studies, which tried to explain and interpret the mind of the autistic child. This work, carried out during the 1960s, culminated in a monograph published in 1970. They were the first to systematically ask questions about the cognitive abilities of severely intellectually impaired children, who had previously been considered untestable and ineducable. In their ingeniously and elegantly designed experiments, they compared learning-disabled children with and without autism, and typically developing children. All were matched for mental age, not chronological age, using a range of cognitive tests, e.g., of memory, vocabulary, and abstract reasoning. This methodology was revolutionary at the time and made visible a variety of cognitive differences, both strengths and weaknesses that could be specifically attributed to autism. Hermelin and O'Connor also studied groups of children with specific disabilities in seeing and hearing, again comparing them with autistic and non-autistic children. In their final working period, they embarked on another pioneering series of experiments into the basis of the previously unexplained phenomenon of savant talent.

O'Connor and Hermelin were the first to apply ideas and methods derived from information processing to the study of autism and are therefore rightly considered the grandparents of modern cognitive theories of autism. They also applied paradigms that were being developed at the same time by neuropsychologists who discovered dissociations of cognitive processes through the study of brain lesions. Thus, Hermelin and O'Connor overcame the limits of purely behaviorist paradigms and were able to probe the neurocognitive causes of the behavioral phenomena of autism. Their legacy is the identification of specific information processing abnormalities over and above cognitive disabilities that are general consequences of atypical brain development.

Short Biography

Beate Hermelin was born August 7, 1919, in Berlin, the daughter of the German Jewish Lawyer

Julius Fliess, who was the brother of Wilhelm Fliess, friend of Sigmund Freud. In 1939 she escaped to Palestine with a boyfriend, while her family survived the war in Switzerland. In 1948 Beate Hermelin arrived with her filmmaker husband, Rolf Hermelin, in London. Here she attended occasional lectures and was recognized as an exceptional student by clinical psychologist Alan Clarke (1922–2011), an authority on intellectual disability, later professor and vice chancellor at Hull University. He encouraged her to read experimental psychology at Reading University and to carry out a PhD on learning and memory in severely learning-disabled children at London University's Institute of Psychiatry. This was when she started her lifelong collaboration with experimental psychologist Neil O'Connor (1917–1997). The equality of their scientific contributions was acknowledged and highlighted by the strict rotation of authorship on their publications. Hermelin was a member of the Medical Research Council Scientific Staff for all of her professional life. After her retirement in ca 1985, she became an honorary professor at Goldsmith College, London University. In 2001 she published a book entitled *Bright Splinters of the Mind*, which, besides a summary of the work on savant talent, also includes autobiographical observations and reminiscences. Beate Hermelin died January 14, 2007.

Despite her pioneering and influential work, and despite her glamorous appearance and her consummate skill in giving inspiring talks, Beate Hermelin eschewed the limelight. Instead she put her lively energy into mentoring her students, many of whom went on to forge distinguished careers in autism research. Among them are Uta Frith, Peter Hobson, Tony Attwood, and Pam Heaton.

Description

The Beery-Buktenica Developmental Test of Visual-Motor Integration (Beery VMI; Beery

and Beery 2010) is a test of visual-motor coordination. Visual-motor integration is “the degree to which visual perception and finger-hand movements are well coordinated” (Beery 1997, p. 19). This paper-and-pencil test involves examinees copying increasingly complex designs. It is designed to assess visual-motor integration, visual perception, and motor coordination skills and is designed to indicate the need for support services for problems in one or more of these areas.

The Beery VMI includes Short and Full Format tests and supplemental Visual Perception and Motor Coordination tests. None of the Beery VMI tests is timed. The Short and Full Format tests involve the examinee copying increasingly complex designs with a pencil without an eraser. Both the Short and Full Format tests can be administered to individuals and groups (e.g., kindergarten class). The Full Format test contains 30 items and is appropriate for use with children (ages 2–18) and adults (ages 19–100). The items increase in complexity from an imitated mark to a three-dimensional star. The Short Format test contains 21 items and is designed for use with children ages 2–7 years old. It takes about 10–15 min to administer the Short Format or Full Format test. The examiner of the Beery VMI must have Examiner B qualifications, which indicates that examiners must have a graduate degree in psychology or a related field or equivalent training to complete the assessment.

The Full and Short Format test form pages contain a table with six blocks; the top three blocks provide examples of the drawing shapes that the examinee is to copy in the corresponding block below. The blocks represent the boundaries within which the examinee is to draw the design. The Visual Perception supplemental test requires examinees to identify a target design among choices, and the Motor Coordination supplemental test requires examinees to trace a geometric shape with a dashed outline using a pencil without an eraser. Each supplemental test takes about 5 min to complete in addition to administration time for the Short and Full Format tests.

The first three items of the Full Format test, which require scribbling, are designed for use with very young children. For the next three

items, the examiner models drawing the first three shapes in the upper blocks of the test form; after each model, the examinee copies the same shape in the lower blocks of the test form. For examinees aged 19–100, testing starts with item 7 and the examinee copies the printed shape, such as horizontal line, vertical-horizontal cross, or square, in the lower blocks of the test form. Testing is discontinued when an examinee draws three items incorrectly in a row.

Because the Beery VMI is a brief assessment, testing typically can be completed in one session. The Beery VMI is a paper-and-pencil test that must be hand-scored by the examiner. Examinees’ drawings are scored 1 or 0 based on the degree to which each drawing met relevant criteria. Accurate scoring requires the use of a protractor to make judgments about accuracy of angles, etc. The examiner’s manual contains many scoring examples and comments about design attempts, which assist with scoring and interpretation of the examinee’s drawings. A total raw score is obtained by adding the number of designs that were scored as “pass.” The examiner’s manual contains tables to convert raw scores into standard scores, percentiles, and age equivalent scores.

Assessment materials include an examiner’s manual, entitled *Beery VMI With Supplemental Developmental Tests of Visual Perception and Motor Coordination For Children and Adults*, and four different scoring forms: Full, Short, Visual Perception, and Motor Coordination. The examiner’s manual contains administration and scoring instructions and age-specific norms, including about 600 age-specific norms for children from birth to age 6. The examiner’s manual also includes teaching suggestions for improving visual-motor coordination skills.

The authors of the Beery VMI, Keith and Natasha Beery, have also produced additional materials beyond the examiner’s manual to supplement the assessment and aid in the development of related skills. The materials include the following:

- (a) Developmental Teaching Activities: a resource that contains 250+ activities that

parents and teachers can use with young children (birth to age 6) to support the development of skills useful for art, academics, and athletic activities

- (b) My Book of Shapes: a resource that contains 100 geometric paper-and-pencil activities that parents and teachers can use with young children (preschool and kindergarten) to support the development of skills, especially useful for supporting visual-motor skills necessary for early literacy and early numeracy development
- (c) My Book of Letters and Numbers: a resource that contains 100 activities for use with children in the second half of their kindergarten year to support the development of skills necessary for literacy and numeracy activities
- (d) Developmental Wall Chart for Visual-Motor Integration: a wall chart with information about development of gross and fine motor, visual, and visual-motor skills for young children (birth to age 6)
- (e) Beery VMI Stepping Stones Parent Checklist: a checklist created for parents to document their children's progress from preschool through early elementary age

Historical Background

The Beery VMI was first developed in 1967 and is currently in its sixth edition. The most recent normative data was collected in 2010 for children and 2006 for adults. The current version of the assessment looks very similar to its original version, with four major changes as part of past revisions. First, the Visual Perception and the Motor Coordination supplemental tests were added in 1997. The addition of these supplemental tests allows the examiner to obtain additional information to identify specific areas of skill weakness. Second, in 2004, the number of items on the Full Format was increased from the original number of 24–30. Third, the norms were expanded to include a wider age range in 2004 and 2006. Finally, scoring was based on a scale of 1–4 between 1989 and 1996; however, the original and more recent versions use a scoring system with only 1 point possible per item.

Psychometric Data

The Beery VMI “is regarded as one of the most valid and reliable instruments for the assessment of visual-motor integration” (Kulp and Sortor 2003, p. 313) and is used internationally. Standardization studies were conducted on the Beery VMI. The most recent standardization sample for children occurred in 2010 using a nationally representative group of 1,737 children between the ages of 2 and 18 years old. The most recent standardization sample for adults occurred in 2006 using a nationally representative sample 1,021 adults ages 19–100. For more information about psychometric data, the reader is encouraged to refer to the *Encyclopedia of Autism Spectrum Disorders* entry entitled “Visual-Motor Integration, Developmental (VMI) test” (authored by Dr. Ted Brown) or *The Beery-Buktenica Developmental Test of Visual-Motor Integration (Beery VMI) with Supplemental Developmental Tests of Visual Perception and Motor Coordination and Stepping Stones Age Norms: Administration, Scoring and Teaching Manual* (Beery and Beery 2010).

Clinical Uses

The Beery VMI is used in a number of settings and by a variety of professionals to assess the visual-motor integration skills of a wide range of people. Settings of use include schools, hospitals, and clinics; professionals who use the Beery VMI include psychologists, occupational therapists, neurologists, etc. Given the number of disabilities and disorders that include symptoms of visual-motor, visual-perceptual, and motor coordination difficulties, the Beery VMI is applicable for use with many people. Autism spectrum disorder (ASD) is one such condition that typically involves motor and visual deficits (American Psychiatric Association [APA] 2000; Coulter 2009). An advantage of using the Beery VMI for assessment of children with ASD is its nonverbal design, which helps to reduce or eliminate language confounds observed with other psychoeducational assessments.

The Beery VMI is a useful tool as part of psychoeducational evaluations because the Beery VMI provides information about children's writing readiness skills and indicates potential deficits in visual-motor functioning that may require intervention, such as occupational therapy. The supplemental tests help teams identify specific visual-perceptual or motor coordination deficits that might not otherwise be identified on the Short and Full Format tests (Kulp and Sortor 2003). Also, given the importance of early identification of developmental delays, the Beery VMI can be used to identify young children's motor coordination and/or visual perception delays. The Beery VMI is especially helpful in early intervention settings because it provides standard scores for children as young as 2 years old, which is rare among psychological assessments. Additionally, the Beery VMI is useful in educational settings because it can be used as part of universal screening, which involves assessing all children (in a class or school) to determine specific needs. Because it is acceptable for use with groups, the Beery VMI can provide educators with information about the skills of children in an entire class in a short amount of time. There is, however, some evidence that the Beery VMI falls short in identifying older children with handwriting dysfunction (Goyen and Duff 2005) despite its standing as a robust instrument in the use of identifying visual-motor integration. As such, clinicians may be cautioned to not rely solely on the Beery VMI when making decisions about older children's handwriting needs. Another limitation of using the Beery VMI with children with ASD and, potentially, other disabilities is the requirement of the examinee to imitate the examiner and/or printed designs. Individuals who lack adequate attention or memory skills might produce work and earn scores on the Beery VMI that reflect a low estimate of their true visual-motor integration ability.

The Beery VMI boasts solid predictive validity. That is, VMI scores of children in kindergarten "predicted with 85% accuracy those children who had reading problems seven years later" (Brown et al. 2009, p. 395). There is evidence

of associations between children's Beery VMI scores and math and reading performance (Sortor and Kulp 2003). The Beery VMI was created to be compatible with the sequential development of children's skills. Beyond the use of identification of children's needs, the instrument is also designed to support the advance of research. The Beery VMI is described as culture-free and nonverbal, making it appropriate for use with a range of individuals, evidenced by the use of geometric forms instead of letters or numbers. However, recent evidence has called into question whether the Beery VMI is truly culture-free. Specifically, research conducted with a South African preschool population suggested differences in scores between children of socioeconomic status (SES) and race (Dunn et al. 2006), with White children and children of higher SES performing better than their counterparts.

Behavior

Marina Azimova

ABA Services of CT, West Hartford, CT, USA

Definition

Behavior is an action or reaction exhibited by a human or animal in response to stimuli. Stimuli may be external and/or internal. Manipulating stimuli is the way to change any behavior. Specific target behavior chosen for modification must be observable and measurable.

Quite simply, behavior is anything a living organism can do.

Definition

Behavior analysis is, “the experimental investigation of variables that influence the behavior of

any living organism” (Mayer et al. 2012, p. 6). Often, it is used interchangeably with applied behavior analysis. While there is a relationship between the two, they are not synonymous. There are three branches of the science of behavior analysis – behaviorism, experimental analysis of behavior (EAB), and applied behavior analysis (ABA) (Cooper et al. 2007). ABA, therefore, is one branch of the science of behavior analysis. In addition to these three branches of the science, there is also a focus on practice guided by behavior analysis.

Historical Background

The question of why people behave as they do has been answered in many ways. Over the centuries, many different belief systems have evolved to explain human behavior, including religion, mythology, astrology, and cultural practices. Psychologists, whose focus is on behavior, have developed varying perspectives and theories regarding the causes of behavior, including structuralism and psychoanalysis.

Eventually, there was an attempt to understand whether human behavior might be investigated using the methods of science. At first, Watson employed what the methods of what he called “methodological behaviorism” (Mayer et al. 2012), relying on direct observation and careful manipulation of variables to determine their influence (if any) on behavior. The unique aspect of Watson’s work was to study behavior as a strict scientist, following the strict rules of scientific process. Other psychologists (e.g., Pavlov, Skinner) followed Watson, adhering strictly to the application of the scientific method to study aspects of the human condition. Through this perspective of science, the field has advanced to the point of acknowledging that human behavior follows the laws of nature as do other phenomena. Behavior analysis has remained true to embracing the role of science in the study of human behavior and that is its unique contribution to psychology and education.

The branch of behavior analysis that later became known as ABA can be traced to a publication by Ayllon and Michael (1959), in which

personnel in a mental hospital were trained to use behavior strategies to modify the behaviors of psychotic residents. Pioneers in the 1960s and 1970s made great inroads to changing behavior despite poor funding, the reluctance of the scientific community to publish their work, and the lack of evidence-based strategies to influence their lines of research. In the field of education, exciting results were found with the use of contingent teacher attention (Hall et al. 1968), token economies (Birnbrauer et al. 1965), and programmed instruction (Bijou et al. 1966).

In 1968, the *Journal of Applied Behavior Analysis* was first published. This has been the premiere journal of the discipline since that time. The journal focuses on the use of within-subject designs to experimentally evaluate the effects of treatments and to experimentally identify controlling relationships between variables. For many years, such within-subject design effects were considered less important than group design effects (which are commonly done, e.g., in psychology). In recent years, there has been some progress in this area, as repeated demonstrations in multiple single case designs are now being recognized as scientific evidence.

Also in 1968, the seminal article on the dimensions of ABA was published (Baer et al. 1968). In this article, the authors outline seven critical elements of ABA that define interventions that are behavior analytic: applied, behavioral, analytic, technological, conceptually systematic, and effective.

Current Knowledge

Behaviorism is the theoretical and philosophical branch of the science. Behaviorists analyze at conceptual levels and create theoretical accounts of behavior that are consistent with existing data. Behaviorists may also outline areas in which empirical data are absent and may suggest ways to rectify gaps in our existing knowledge. Behaviorists inspire much of the work of the other branches, and they maintain the focus of the science on the theoretical underpinnings and philosophical stances.

The experimental analysis of behavior (EAB) is the basic science branch. These individuals design and conduct experiments in basic science. They conduct experiments in laboratories and other highly controlled environments. They may use human or nonhuman participants. In their work, they may discover and clarify basic principles of behavior, and they may identify functional relations between variables. EAB is also the branch that creates many of the questions for both ABA and EAB to pursue.

Applied behavior analysis is the branch of behavior analysis in which the tactics derived from the principles of behavior are applied to improve socially significant behavior, and experimentation is used to identify the variables responsible for the improvement in behavior (Cooper et al. 2007). Applied behavior analysts conduct experiments that are designed to identify relations between socially significant behavior and its controlling variables. They do this to add to the technology of humane and effective behavior change procedures.

All three branches of the science are essential, and they influence one another. Research is an essential component to the advancement of the science. Both basic and applied researches help to refine concepts and develop effective procedures/interventions.

The main methodologies utilized within behavior analysis are within-subject designs. These designs experimentally prove the controlling relationships between independent and dependent variables and rule out extraneous explanations. Several commonly used ones are frequently used in behavioral publications: the reversal design, the multiple baseline design, the changing criterion design, and the alternating treatments design.

The Reversal Design: In the reversal design, data on the target behavior are collected prior to intervention (condition A), the intervention is applied (B), the intervention is withdrawn (A), and the intervention is reapplied (B). This is referred to as an ABAB design. The impact of an intervention is examined for its controlling influence. Is it the variable responsible for the change? Does the behavior revert back to pretreatment

levels in the absence of treatment? In this way, one can be more confident that it is the treatment itself effecting change. Variations of the design exist (e.g., ABA, BABA). However, all of the reversal designs use this basic premise of reversing the effect of the intervention by withdrawing treatment.

The Multiple Baseline Design: In this design, the intervention is applied in sequential phases across participants, behaviors, or settings. Essentially, the researcher looks for replication of effect. If an intervention is first applied to one student with good impact, can it then be extended to others? Similarly, can it be applied across settings? If an intervention successfully taught one skill, can it be extended to another? In this way, the confidence about the utility of this intervention in this context increases.

The Changing Criterion Design: In the changing criterion design, the criterion for behavioral effect continually increases. In this design, behaviors may be changed gradually, with increases in expectations shifting over time.

The Alternating Treatments Design: In this design, different approaches or interventions can be directly compared. The level of the target behavior can be compared in different conditions. In other words, the dependent variable is compared in different levels or variations of an independent variable. If there is a question about whether a particular independent variable will make a difference, it can be compared to no treatment. If there is a question about the level of intervention to apply (e.g., # minutes of an activity, richness of reinforcement ratio), the question can be experimentally answered to guide treatment.

In all behavioral research, as well as in applied work inspired by behavioral research, clinicians remain committed to the identification of functional relationships. When appropriate, they utilize within subject designs. This is especially true when they are evaluating the impact of a more experimental treatment. At the level of the individual, the behavior analyst always seeks to demonstrate functional relationships, to identify variables responsible for change.

The delivery of behavior analytic services is a separate domain, as noted above, but is closely

linked to this third branch of the science of behavior analysis, ABA. Practitioners design interventions and evaluate their impact. They use procedures that are derived from basic research and that have been shown to produce socially significant outcomes by applied researchers. In recent years, this application of the science has become increasingly prominent. The effectiveness of ABA in effecting change has been significant, especially in certain populations, such as individuals with autism. This has created a unique and wonderful opportunity for ABA to receive attention in the broader public arena. It has also created threats to the purity of the science, to the portrayal of the science, and to the public's understanding of the core characteristics and commitments of ABA. Misconceptions and misrepresentations abound, and the correction of these misconceptions and misrepresentations has become imperative.

Many myths and misconceptions exist about behavior analysis and, in particular, about behavior analysis in application to clinical practice. In general, the field is often presented as reductionistic and is often contrasted with more humanistic approaches that have more broad appeal. This is a major challenge to the science of behavior, as it impedes the ability to offer these powerful interventions to those most in need of them. Professionals within the applied arena often struggle with core misunderstandings of the science and its applications. In addition, they often are presented with clinical contexts that are ethically challenging. For example, many behaviorally based clinical programs are diluted, combined with other nonverified approaches or delivered at a level of intensity not associated with likely success. There is a need for all branches of the science to promote the accurate and current state of the field, in research and clinical arenas.

Applied refers to the commitment of ABA to improving the lives of those they serve. Behavior analysts seek to effect changes that are socially significant. To achieve this, they select behaviors that are of importance to the individual and to their family. They also assess whether changes have made real-world differences in the lives of the individuals. Many misconceptions exist about

this particular dimension, as many people think of ABA as intervening on all behaviors or as being focused on behavior reduction in the absence of an analysis of importance. In the early days of ABA, when impact was new, the focus was on using the science to reduce intractable behaviors. However, the science has evolved over many decades and is now very focused on the importance of targeting behaviors that make a real-world difference.

Behavioral refers to the focus on behavior. Behaviors targeted must be those in need of improvement, must be measurable, and must be verified to have changed through objective means. This guideline emphasizes the need to target and measure behaviors in the natural setting of the individual and commits the behavior analyst to using behavioral techniques for all intervention and measurement. It distinguishes ABA from other service providing disciplines that often speak in generalities and in global terms. The commitment to the science requires that all behaviors must be measurable, operationally defined, and thoroughly evaluated objectively for change that is empirically verifiable.

Analytic refers to the demonstration of a relationship between the manipulated variables and the documented behavioral effects. Experimenters must be able to control the occurrence and non-occurrence of the behavior. Behavior analysts value this dimension very highly and work to prove that such a functional relation exists between the independent variable (variable that was manipulated) and the dependent variable (behaviors targeted). The behavior analyst is never content with change alone; there must be an understanding of WHY the behavior changed, of the variables responsible for the change.

Technological refers to replicability. Behavior analysts use precision, detail, and clarity in describing their interventions so that others can replicate their work. Behavioral procedures must be replicable to be teachable to others. From both a research and clinical perspective, then, the technological dimension is essential to behavior analysis. This is another hallmark characteristic of science. If a technique is not technological, it cannot be subjected to a test. It then becomes

analogous to anecdotal reports, and it becomes vulnerable to exaggeration and false claims. The requirement for procedures to be technological ensures that they are both teachable and testable.

Conceptually systematic refers to the foundations of behavior analysis. Applied behavior analysts describe their procedures and the impact of these procedures in terms of the basic principles of behavior. This dimension refers to the need for behavior analysts to stay close to their science, to link their findings back to the elemental principles of behavior, and to guard against adding superfluous and false explanations. This principle guards against the dilution of the science at the conceptual and explanatory level.

Effective refers to a core commitment to the improvement of behavior to a practical and meaningful extent. Behavior analysts do not value statistical significance or theoretical significance as much as they value social significance. Effective also implies that behavior analysts choose interventions with empirically verified effects, do not choose interventions that are unproven, and discourage the continuation or pursuit of baseless interventions. In recent years, this has taken the form of commitment to evidence-based practice. While behavior analysts have always valued this dimension, its importance has increased in the context of fad treatments and false claims of effectiveness.

Generality refers to the tendency for behavior changes to last over time, appear in untrained environments, and spread to untrained behaviors. If behaviors are not maintained and do not extend, the changes are far less significant. Behavior analysts are committed to teaching behaviors with enduring and transferrable qualities. In the earliest days of behavioral intervention, this dimension was not as prominently emphasized as it has been in recent years. Demonstration of the generality of behavior change is now routinely expected and sought.

In addition, behavior analysis is defined by several central constructs. Determinism implies that we can determine the cause and effect of various occurrences and can determine the variables responsible for change. Behavior is lawful, and functional relationships can be identified.

Philosophic doubt implies a skeptical worldview. Behavior analysts require empirical verification of hypotheses and do not embrace conclusions without confirming evidence. Parsimony implies that behavior analysts resort to the simplest explanation for events, the explanations that require the least inference and speculation. They stay close to the data and do not go beyond the data in explaining their results.

The strength of the science of behavior analysis comes from commitment to these dimensions and constructs. Furthermore, the integrity of the science depends upon the commitment to the continued development of and adherence to these dimensions and constructs in all branches of the science. Behaviorism, experimental analysis of behavior, and applied behavior analysis are inter-related, and the dimensions of the science fuel and further define one another.

Future Directions

Due to its adherence to the methods of science, behavior analysis has resulted in great strides in understanding, identifying the environmental variables that influence a wide variety of animal and human behavior. One of the areas of the biggest impact has been on persons with disabilities. Acknowledging the benefit of this particular perspective in studying human behavior, future directions of the application of behavior analysis should proceed in at least three directions. First, behavior analysts continue to sharpen its analysis of human behavior in the areas in which they have already studied. For example, deeper analysis of how to treat disabilities would provide significant clinical benefit, as has been shown already. Second, behavior analysis should branch out into other areas of human behavior not yet well studied and submit those areas to extensive scientific analysis. Some of these new areas could include analysis of human creativity and psychological disorders, such as obsessive-compulsive behavior. Third, behavior analysis should proceed more diligently in applying findings from experimental behavior analysis to the testing of and solutions for human behavior. This “translational”

research, in which experimental findings are tested in the human/applied area, has the potential for great payoff.

Behavior Analyst Certification Board

Mary Jane Weiss and Samantha Russo
Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Behavior Analyst Certification Board®

The Behavior Analyst Certification Board®, Inc. (BACB®) is a nonprofit corporation established in 1998 to meet professional credentialing needs

identified by behavior analysts, governments, and consumers of behavior analysis services. The BACB's mission is to develop, promote, and implement an international certification program for behavior analyst practitioners. The BACB has established uniform content, standards, and criteria for the credentialing process that are designed to meet:

1. The legal standards established through state, federal, and case law
2. The accepted standards for national certification programs
3. The “best practice” and ethical standards of the behavior analysis profession

Prior to the creation of the BACB, no uniform standards existed for evaluating the education, training, and experience of a behavior-analytic service provider. Since its inception, the BACB has set the standards for education and training in the field of applied behavior analysis and has certified more than 25,000 individuals (as of 2017).

The BACB adheres to the national standards for organizations that grant professional credentials. The BACB certification procedures and examination content undergo regular psychometric review and validation, pursuant to a job analysis survey of the profession and standards established by content experts in the field.

In 2015, in order to better control experience hours, all BCBAs were required to complete and pass a supervision training curriculum. This change was also supplemented by the change in degree requirements of 2016. In order to be qualified to be a BCBA, the individual must hold a master's degree in behavior analysis, psychology, or education. Other related fields, which were previously accepted by the BACB, are no longer accepted.

The BACB offers four different credentials, BCBA-D, BCBA, BCaBA, and RBT. The RBT credential went into effect in 2016. With the addition of the RBT credential, the BACB became the only organization in the field of behavior analysis to offer credentials at every educational level (graduate, undergraduate, and high school).

The Behavior Analyst Certification Board's BCBA, BCaBA, and RBT credentialing programs are accredited by the National Commission for Certifying Agencies, the accreditation body of the *Institute for Credentialing Excellence*. The BACB is endorsed by the *Association of Professional Behavior Analysts*, the *Association for Behavior Analysis International*, Division 25 (Behavior Analysis) of the American Psychological Association, and the *European Association for Behaviour Analysis*.

The most up-to-date information on the BACB can be found at www.bacb.com.

Behavior Assessment System for Children, 2nd Edition

Felice Orlich

Autism Psychology Services, Seattle Children's Hospital CAC – Autism Center, Seattle, WA, USA

Synonyms

[BASC-2](#)

Definition

Acronym: BASC-2

Author: Kamphaus, Randy W.; Reynolds, Cecil R.

Purpose: Designed to determine behavioral and emotional functioning in children and adolescents in preschool through high school

Administration time: 10–20 min (teacher: TRS and parent: PRS), 30 min (self: SRP)

Scores: Scores/Interpretation: T scores and percentiles for general population and clinical populations

Ages/grades: Ages: 2:0 through 21:11 (TRS and PRS); 6:0 through college age (SRP). English and Spanish forms are available.

Scoring/administration programs: BASC-2 ASSIST and ASSIST-plus provide scoring,

reporting, and relationship to DSM-IV-TR diagnostic criteria. Online administration, scoring, and reporting are available for the TRS and PRS scales.

Publisher: Pearson

Publisher address: Pearson, 19500 Bulverde Road, San Antonio, TX 78259; Telephone: 800-627-7271; FAX: 800-632-9011; E-mail: pearsonassessments@pearson.com; Web: www.pearsonassessments.com.

The Behavior Assessment System for Children, 2nd Edition (BASC-2) is a commonly standardized set of rating scales and forms used to assess behavior in children and adolescents. The BASC-2 is normed on current US census population characteristics. Specific norms are not available for individuals with autism spectrum disorders (ASD) or neurodevelopmental disorders. Available scales include the Teacher Rating Scales (TRS), Parent Rating Scales (PRS), Self-Report of Personality (SRP), Student Observation System (SOS), and a Structured Developmental History (SDH).

The Teacher Rating Scales (TRS) measure adaptive and problem behaviors in the pre-school or school setting. Teachers or other qualified observers can rate specific behaviors on a four-point scale of frequency, ranging from "Never" to "Almost Always." The TRS contains 100–139 items. The Parent Rating Scales (PRS) measure both adaptive and problem behaviors in the community and home setting. The form requires a fourth grade reading level and is available in Spanish. Similar to the TRS, parents or caregivers can complete forms at three age levels – preschool (ages 2–5), child (ages 6–11), and adolescent (ages 12–21). The PRS contains 134–160 items and uses a four-choice response format. Both scales capture internalizing and externalizing behavioral adjustment reflected in an overall Behavioral Symptoms Index (BSI). Scales uniquely applicable to children and adolescents with ASD include assessment of functional communication and social skills.

The Self-Report of Personality (SRP) provides self-assessment of a child or adult's thoughts and feelings. Each form – child (ages 8–11), adolescent

(ages 12–21), and college (ages 18–25) – takes about 30 min to complete. The SRP-Interview (SRP-I) form for children 6–7 provides simple yes-or-no responses to questions asked by an examiner. The SRP-I takes about 20 min to complete. Spanish versions are available for the child and adolescent forms. In addition to measuring, internalizing (depression/anxiety/self-esteem), and externalizing problems (impulsivity/attention), the SRP offers self-assessment of interpersonal relationships and social stress.

Recent validity studies of the BASC-2 for use in individuals with ASD have found that the BASC-2 TRS and PRS forms can be effective in differentiating between children with high-functioning autism and typically developing peers. In a recent study (Ensign 2010), significant differences were found between individuals and typically developing groups on all PRS scales. DSM-IV-TR screening indices suggested that the Developmental Social Disorders Scale was highly effective in differentiating between the two groups. Hass et al. (2010) found similar results on the TRS in children receiving an educational classification of autism spectrum disorder.

Behavior Development Questionnaire

Corey Ray-Subramanian
Waisman Center, University of Wisconsin-Madison, Madison, WI, USA

Synonyms

BDQ; Wing Subgroups Questionnaire (WSQ)

Description

The Behavior Development Questionnaire (BDQ), formerly referred to as the Wing Subgroups Questionnaire, is an assessment tool used to classify individuals with autism spectrum disorders into one of three categories based on Wing and Gould's (1979) categorization scheme: *aloof*, *passive*, and *active-but-odd* (Castelloe and Dawson 1993). These classifications are distinguished based on the individual's quality of social interaction. The *aloof* group is considered to rarely display spontaneous social approaches to others, other than for the purpose of making requests, and often rejects social contact from others. The *passive* group shares this lack of spontaneous social approaches but does not reject social approaches from others. The *active-but-odd* group is described as being willing to make social approaches to others, but the approaches are considered unusual in quality (Castelloe and Dawson 1993).

The BDQ is a parent- or teacher-completed questionnaire that is comprised of 13 groups of four behavior descriptions. The 13 groups cover various domains such as patterns of social approaches, response to social approaches,

communication skills, imitation, play skills, unusual motor behavior, resistance to change, physical coordination, and challenging behaviors (Castelloe and Dawson 1993). Parents or teachers are asked to rate the frequency with which the target individual's behavior fits the described behavior (0 = never; 6 = always). An example item is "When my child is with unfamiliar adults or children he readily approaches others to interact and responds easily to others. His manner of interacting is generally appropriate (not awkward or unusual)" (Castelloe and Dawson 1993; p. 240). Summary scores are calculated for each of the four groups (i.e., *aloof*, *passive*, *active-but-odd*, *typical*) by totaling the scores across the 13 groups of behavior descriptions. The group for which the individual receives the highest summary score is assigned as the overall classification (Castelloe and Dawson 1993).

Historical Background

The BDQ was first reported in published research by Castelloe and Dawson (1993), and, at that time, the questionnaire was referred to as the Wing Subgroups Questionnaire, as it is based on clinical subgroups within ASD introduced by Wing and Gould (1979). Wing and Gould developed the classifications to help improve understanding of the relationships between typical autism, mental retardation, and other conditions involving social impairment.

Psychometric Data

Evidence for the validity and reliability of the BDQ has been provided through the examination of the questionnaire's internal consistency, the distinct nature of the three clinical subgroups (i.e., *aloof*, *passive*, *active-but-odd*), interrater agreement, and relationships between BDQ results and other concurrent measures. Internal consistency, as measured by Cronbach's alpha, has been shown to range from .63 for the *passive* classification to .85 for the *active-but-odd*

category on parent-completed questionnaires. For teacher-completed BDQs, Cronbach's alpha has been found to range from .54 for *passive* to .79 for *active-but-odd*. Clinicians' assignments of children with ASD to Wing's groups have been shown to be highly correlated with the results of parent-completed BDQs (Castelloe and Dawson 1993).

Evidence for the distinct nature of the three groups has been found in the strong negative correlation between the *aloof* and *active-but-odd* groups (−.70 for parent-completed BDQs and −.55 for teacher-completed BDQs) and the low correlations between *aloof* and *passive* (−.02 for parent-completed BDQs and −.04 for teacher-completed BDQs) and between *passive* and *active-but-odd* (.17 for parent-completed BDQs and .13 for teacher-completed BDQs; Castelloe and Dawson 1993; O'Brien 1996). However, item analysis has shown that 16 of the 50 items on the BDQ poorly discriminate among the subtypes (O'Brien 1996).

The *aloof* classification has been shown to be associated with lower IQ, lower receptive language skills, and more severe symptoms of autism (Castelloe and Dawson 1993), as compared to the other two classifications. Significant differences have also been found between the *aloof* and *active-but-odd* groups on the Peabody Picture Vocabulary Test and the Vineland Communication and Socialization domains (O'Brien 1996). The *passive* group has been shown to obtain lower Maladaptive Behavior scores on the Vineland and have less physical aggression reported on the Autism Behavior Checklist compared to the other two groups (O'Brien 1996). Wing's subgroup classifications based on clinicians' judgments have been associated with differences in brain activity measured through electroencephalography (EEG; Dawson et al. 1995). In one study, levels of active-but-odd behaviors on the BDQ did not distinguish children with high-functioning autism from a group with ADHD or ODD (Downs and Smith 2004). The ADHD/ODD group actually displayed more *aloof* behavior than the high-functioning autism group (Downs and Smith 2004).

Interrater reliability coefficients, based on pairs of teachers and teaching assistants completing the BDQ for a particular child, were found to be .60 for the *aloof* group, .81 for the *passive* group, .77 for the *active-but-odd* group, and .78 for the *typical* group (O'Brien 1996).

Clinical Uses

The BDQ can be used by clinicians to categorize individuals with ASD as *aloof*, *passive*, or *active-but-odd* and plan intervention goals appropriately (Castelloe and Dawson 1993). It has also been used as an outcome measure in clinical intervention research, and BDQ scores have been found to change following early intervention (Downs et al. 2007). To date, little has been published on the specific clinical uses of the BDQ.

Behavior Modification

Michael D. Powers

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Behavior modification is a treatment approach based on Skinner's (1938, 1953) principles of operant conditioning. It seeks to establish desirable behavior and reduce or eliminate undesirable behavior through the use of empirically validated procedures, including but not limited to positive and negative reinforcement, extinction, and punishment. Behavior modification procedures have been used to treat a wide variety of human problems including attention deficit hyperactivity disorder, autism, enuresis and encopresis, fears and phobias, noncompliant behavior, and pica, among others.

BOS

Description

The Behavior Observation Scale (BOS) is a clinician-based measure of behaviors associated with autism (Freeman et al. 1978). The authors emphasized that children with autism should be studied within a development context and compared to nonspectrum typical and intellectually impaired children to distinguish behaviors specific to autism that are of diagnostic significance (Freeman et al. 1980).

The BOS is a checklist of 67 objectively defined behaviors. The clinician watches the child interact with age-appropriate toys through a one-way mirror in the presence of an examiner. The observation consists of recording the frequency of the specified behaviors in nine 3-min intervals. Three-minute baseline periods are also documented at the beginning and end of the play period. The examiner in the room presents the child with standard stimuli for seven of the intervals. During one interval, the examiner actively tries to engage the child through ball play. The behaviors are scored as not present or occurring once, twice, or continuously during the three-minute intervals. When not following these specific prompts, the examiner sits in one corner of the room and does not respond to the child if he or she initiates contact (Morgan 1988).

Historical Background

The BOS was one of the first diagnostic instruments for autism. Unlike other diagnostic

measures, the BOS was the first autism scale to emphasize the importance of controlling the observed behaviors of a child, as well as the environment in which the observation took place. The frequency of these observed behaviors was used to differentiate among diagnostic groups. The appearance of some specific rare behaviors during play was found to be a significant indicator, suggesting that the quality of some specific behaviors, rather than the frequency, was more important to diagnose children with autism (Lord and Corsello 2005).

Psychometric Data

The authors of the first factor analyses of the BOS concluded that it is necessary to create age-specific norms for the frequencies of behaviors of children with autism. These norms still need to be created comparing age-matched groups of both nonspectrum typical and intellectually impaired children (Freeman et al. 1978).

Some measures of reliability have been completed for the BOS. Interrater reliability of the BOS was assessed with a sample of 89 children, which included 36 with autism and 30 with nonspectrum intellectual disabilities matched for mental age and 23 typically developing children (Freeman et al. 1978). Correlation coefficients for ratings by the observer (watching through a one-way mirror) and the examiner (sitting in the room) were greater than 0.84 for 55 of the 67 behaviors; the published work did not include the coefficients for the remaining 12 items (Morgan 1988). Internal consistency and test-retest reliability have not been reported for the BOS (Parks 1983).

Various studies have also examined the validity of the BOS. The content validity of the BOS comes from the inclusion of ratable behaviors related to the clinical diagnostic criteria of autism. This is demonstrated by a factor analysis performed from three groups of children: those with autism, those without autism but with intellectual disability, and those with typical development (Freeman et al. 1980). According to their analyses, the authors characterize children with autism as exhibiting “inappropriate interactions

with people and objects,” the nonspectrum intellectually impaired group as having “solitary behaviors,” and the typically developing group as showing “appropriate interactions with people and objects” (p. 344).

In order to determine discriminate validity, Freeman and colleagues compared groups of children with autism and children without autism but with intellectual disabilities and found that they only differed on 11 of the 67 behaviors that compose the BOS (Freeman et al. 1979). However, the authors point out that the behaviors that did not discriminate between these groups were dependent on the developmental variables of mental and/or chronological age. Freeman and Ritvo (1980) compared children with autism, cognitively impaired children matched for mental age, and typically developing children matched for chronological age on the BOS. They found that six items differentiated the low-IQ autism group from the cognitively impaired group. They concluded that the three groups could be discriminated with the BOS if these six items were coded. No studies have examined how well the BOS distinguished between children with autism and children with other behavior problems (Morgan 1988).

Clinical Uses

The purpose of the BOS is to diagnose autism based on objective observation of behavior within a developmental context (Morgan 1988). Though the intention of the authors was to create an agreed-upon diagnostic framework for use in research (Freeman et al. 1978), the BOS is useful clinically as well. Freeman et al. add that the BOS can also be used to document changes in symptoms over time. Diagnosis and symptom changes are necessary for providing adequate therapeutic care for any individual with behavioral or cognitive difficulties, and the BOS provides the means for obtaining that information.

Behavior Plan

Jessica Rohrer

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

A behavior plan (behavior support plan or behavior intervention plan) is an organized plan to aid in the reduction of problem behaviors and/or increase desired behaviors. Behavior plans are documents which are usually developed by behavior analysts, teachers, counselors, and school psychologists, of with input from the individual themselves and/or their parent. The documents are suitable for implementation in various settings, such as private homes, public or private schools, residential facilities, or vocational facilities.

Historical Background

In the 1970s, the primary focus of behaviorism and behavior modification shifted from primarily using aversive procedures to eliminate undesirable behaviors toward the use of reinforcement-based techniques to increase desired behaviors (Brown 1987). In many ways, this shift increased the quality and effectiveness of behavioral interventions, as they became more widely accepted and utilized and began to be implemented across individuals with diverse behavioral profiles.

Current Knowledge

Behavior plans may incorporate various methods of behavior modification and are individualized for each person. The procedures outlined in behavior plans should be developed based on evidence-based techniques, such as functional behavior assessment or experimental functional analysis (see Functional Analysis). The behavioral functions identified using these methods are then used to develop an appropriate behavior plan.

The objectives of developing a behavior plan include identifying and defining target behaviors, recommending procedures to decrease challenging behaviors, and recommending procedures to increase appropriate behaviors or replacement skills.

Behaviors targeted to decrease and those targeted to increase must be clearly and operationally defined, so that all personnel implementing the plan will do so consistently. These definitions should be observable, clear, concise, and accurate.

If a behavior plan involves procedures to decrease challenging behaviors, it will necessarily include methods to teach or increase appropriate and functionally equivalent responses.

Behavior plans may include several parts, including antecedent strategies, identified behaviors to decrease, identified behaviors to increase, reinforcement systems, management strategies, data collection procedures, protocols for monitoring effectiveness of interventions, strategies for

maximizing generalization and maintenance, and criteria to discontinue.

Antecedent strategies, or antecedent control procedures, are procedures in which antecedents (i.e., environmental cues, discriminative stimuli, establishing operations, or response effort) are manipulated to influence a desired or undesired behavior. Antecedent strategies may include such techniques as clear delivery of directives, breaking tasks down into smaller components, providing and reviewing visual schedules, reviewing contingencies and expectations prior to each task, providing sequencing choices, providing opportunities for sensory activities, delivering reinforcement for appropriate behavior, providing warnings prior to transitions, modifying academic tasks to match student's ability, and making environmental manipulations. These manipulations may include arranging the environment to decrease the likelihood of problem behavior (e.g., clearing area of extraneous materials or positioning the individual away from dangerous materials). Antecedent strategies can be diverse and individualized for each individual.

Procedures designed to decrease problem behavior and increase replacement skills often include a reinforcement-based system. Examples of positive reinforcement-based systems are token economy systems (based on differential reinforcement), where individuals earn tokens (to be exchanged for identified reinforcers) based on the absence of problem behavior and/or engagement in alternative behaviors. In order to identify effective reinforcers, preference or reinforcer assessments should be conducted. These assessments may be informal, such as interviews or anecdotal reports from parents or caregivers or observation of the individual in various environments to determine where he/she allocates time. Preference or reinforcer assessments can also be formal, using a validated assessment such as a forced-choice preference assessment (Fisher et al. 1992) or multiple-stimulus without replacement (MSWO) preference assessment (DeLeon and Iwata 1996).

Once reinforcers have been identified, a token economy system might be considered as a procedure within a positive reinforcement-based behavior support plan.

A token economy could be based on a DRO (differential reinforcement of other behavior), DRA (differential reinforcement of alternative behavior), or DRI (differential reinforcement of incompatible behavior). In a DRO procedure, reinforcement is delivered solely for the absence of problem behavior, whereas in DRA or DRI procedures, reinforcement is delivered contingent on the occurrence of an alternative response or one that is incompatible with the target behavior. A token system could include tokens that can be physically manipulated by the individual (e.g., stickers, coins, or tickets), or they could simply be checkmarks on a list of completed tasks.

Some positive reinforcement-based procedures may not be as specific or structured as a differential reinforcement procedure and may not involve tokens at all. That is, direct reinforcement may be delivered on a fixed or variable schedule, contingent on appropriate behaviors. Positive reinforcement-based procedures can be implemented on their own or in conjunction with a number of other behavioral intervention procedures.

Additional consequence-based interventions may include procedures such as time-out, response blocking or interruption, physical or verbal redirection, response cost or removal of privileges, restitution, and overcorrection. These procedures involve various behavioral concepts such as extinction and may utilize principles of punishment. Therefore, they are typically used in conjunction with positive reinforcement-based procedures, so as not to focus only on the decrease of aberrant behavior but also the increase of appropriate behavior.

Time-out is a procedure which decreases problem behavior by removing reinforcement contingent on the occurrence of the target behavior(s). Time-out can be inclusionary (the individual remains in the same environment) or exclusionary

(the individual is removed from the environment in which the behavior occurred). It is a punishment-based procedure because a stimulus (reinforcement) is removed contingent on problem behavior, therefore reducing the future likelihood of the occurrence of that behavior.

Response blocking attempts to reduce the reinforcing aspects of the behavior by eliminating contact with the reinforcer. For example, an automatically maintained behavior such as hand flapping would be blocked, therefore restricting access to the reinforcing aspects of the behavior. In a response-interruption procedure such as a “hands-down” procedure, the response is interrupted, and the individual is physically redirected to an alternate response (i.e., putting hands down). This procedure may also function due to the principle of punishment, as the individual may engage less frequently in the behavior in order to avoid the redirection procedure.

Response cost, or removal of privileges, is another consequence-based procedure where a reinforcer (or multiple reinforcers) is removed contingent upon the occurrence of the target behavior. The future of occurrence of the target behavior is then decreased, as the individual avoids coming in contact with this aversive contingency. Restitution and overcorrection are typically used with behaviors where the environment is disturbed, such as property destruction, and refer to procedures where, contingent on the problem behavior, the individual is required to restore the environment to its original state. For example, if the individual dumps juice on the floor, he/she would be required to wipe it up. In overcorrection, the individual might be required to not only clean up the spilled juice but also wipe the rest of the floor.

Within any behavior plan should be a defined system for collecting data, including procedures appropriate to the behaviors being measured. Data collection methods may include event recording, duration recording, latency recording, or interval recording. Event recording refers to a count of behaviors as they occur. When reporting these data, it can be summarized as the total number of

behaviors that occurred, the rate of responding (frequency over time), or percentage of the occurrence of the target behavior as compared to other behaviors. Duration recording refers to how long an individual engages in a certain behavior. This can be reported as total duration per episode, per day, or some other specified time period. Latency recording refers to the amount of time between a stimulus and a response. For example, this type of recording may be used to examine how long it takes an individual to respond once an instruction has been given. Interval recording measures the presence or absence of a target behavior within specified time intervals. Whole interval, partial interval, and momentary time sampling are all types of interval recording. To determine which data collection method to use, it is important to look at the characteristics of the behavior and select a data collection method that will best represent the feature that is to be examined.

Data collection is a crucial part of an effective behavior plan, as it allows careful analysis of the target behaviors as they are influenced by the interventions put in place. Data sheets can be developed by the author of the behavior plan or by staff or caregivers implementing the plan. Once a data collection system has been established, all staff and caregivers involved in the plan's implementation must be aware of the procedures. It is important that the terms and methods for data collection have been reviewed by all people that will be involved in data collection, as this will increase the likelihood that the data collected are valid and useful in analyzing the success of the treatments. All people implementing a behavior support plan should be fully trained in all aspects of the interventions. A system to measure and track treatment fidelity should be in place to minimize procedural drift. Procedural drift refers to when, over time, certain interventions or parts of interventions are not carried out as they should be. This inconsistency can affect the success of the behavior plan and may result in some or all interventions losing effectiveness. Treatment fidelity checks can minimize procedural drift by putting into place specific measures to evaluate the implementation of the plan across implementers.

Future Directions

The individuals who develop behavior plans should always consider the ethical responsibilities involved in any behavior modifications and continue to explore positive reinforcement-based methods before those considered more aversive. Behavior Plans should incorporate the input of the individual and/or their parent whenever possible, to ensure a person-centered treatment plan. As the field of behavior analysis progresses, behavior plans should incorporate the most recent behavioral technologies to best support individuals. Currently, behavior plans are commonly utilized in the field of behavior analysis for individuals with autism and other developmental disabilities. In the future, behavior plans can be used to guide and support the efforts of those who work not only with developmentally disabled individuals but with people of all backgrounds who may benefit from behavioral strategies.

Behavior Rating Instrument for Autistic and Atypical Children (BRIAAC)

Sarah Butler¹ and Catherine Lord^{1,2}

¹Center for Autism and the Developing Brain, New York-Presbyterian Hospital/Westchester Division, White Plains, NY, USA

²UCLA, Los Angeles, CA, USA

Synonyms

BRIAAC

Description

The Behavior Rating Instrument for Autistic and other Atypical Children (BRIAAC) was created for the purpose of diagnosing autism (Ruttenberg et al. 1974). The measure was based on observations in a day treatment program of children with autism who had been diagnosed using Kanner's (1943) autism criteria. The measure consists of eight subscales that are completed by a trained examiner who has observed the child for an extensive period of time. The observations lead to descriptive ratings for each subscale within the range characteristic of a 3.5- to 4.5-year-old typically developing child compared to those that are characteristic of a child with severe autism.

Historical Background

The BRIAAC was one of the earliest measures of autism created shortly after Rimland's first diagnostic checklist (Lord and Corsello 2005; Rimland 1964). It was the first measure of autism to utilize direct observation of behaviors as described in the case notes of defined raters, making it a significant milestone of behavior-based measures (Parks 1983).

Psychometric Data

The BRIAAC consists of eight scales that are developmentally ordered, with the lowest level representing behaviors uniquely associated with autism and the highest level representing developmental accomplishments typical of normal 4-year-old children. The scales are communication, drive for mastery, vocalization and expressive speech, sound and speech reception, body movement, social functioning, psychosexual development, and relationship; in the 1977 edition, social functioning and psychosexual development were renamed social responsiveness and psychobiological development, respectively (Ruttenberg et al. 1974). The purpose behind the scoring system is to reflect the entire range of possible behavior and the importance of each behavior within this range (Ruttenberg et al. 1966).

The interrater reliability of the original version of the BRIAAC was examined using trained students as raters (Ruttenberg et al. 1966). Spearman rank correlation coefficients for the four-core scales ranged from 0.85 to 0.88, demonstrating high agreement among raters. However, since all of the children observed had been previously diagnosed with autism, the high reliability does not indicate the ability to diagnose autism accurately with the BRIAAC (Ruttenberg et al.).

Two of the authors also examined the BRIAAC's interrater reliability using the scores of 113 children with autism as determined by seven different pairs of raters (Wenar and Ruttenberg 1976). The correlation coefficients ranged from 0.85 to 0.96 across the eight scales, indicating moderate interrater reliability, as they did not control for response frequencies.

Factor analysis completed by Wenar and Ruttenberg also supported internal consistency because they found a high loading on one factor, which they described as resistance to participation in activities, such as interacting with others or the environment (1976). Cohen et al. also performed factor analysis and similarly found that the same factor accounted for 69% of the variance. All scales, except psychosexual development, loaded at 0.80 or higher, suggesting high internal

consistency (Cohen et al. 1978). This shows that the test is, in fact, measuring a unity factor, leading to high internal consistency.

Both the items and the subscales of the BRIAC were based on frequent observations of children with autism in a daycare center by a highly trained team of specialists. Their observations were incorporated into the items and scales, resulting in good content validity (Wenar and Rutterberg).

The BRIAC presumably has good construct validity because it is based on Kanner's autism criteria (1943), and the children observed were diagnosed according to those same criteria (Morgan 1988). In addition, as previously mentioned, factor analysis demonstrated that the BRIAC does examine one core factor, the resistance to engage with others and the environment (Wenar and Rutterberg; Cohen et al.).

Concurrent validity was studied by comparing the BRIAC scores and clinicians' ratings of 26 children either with autism or typical development (Wenar and Rutterberg). Significant correlations were established between the clinicians' rating and the total BRIAC scores ($r = .69$) and three subscale scores (relationship to an adult, $r = .43$; vocalization and expressive speech, $r = .64$; sound and speech reception, $r = .65$). The authors viewed the examined concurrent validity as satisfactory and expressed the desire to examine the remaining subscales in the future.

Cohen et al. examined the discriminant validity of the BRIAC and found that the total scores did not effectively discriminate among the diagnostic groups of primary-childhood autism, secondary-childhood autism, early-childhood psychosis, developmental aphasia, and mental retardation (1978).

Clinical Uses

The scoring system that addresses the whole range of possible behaviors is clinically relevant because it identifies both signs of progress and problem behaviors (Rutterberg et al. 1966). These areas of needed improvement can be specific for each child evaluated. In addition, the

levels of the scales assist in planning therapeutic programs for children with autism because they indicate upcoming developmental steps and how therapy can progress to meet the child's developmental needs.

Behavior Rating Scale (BRS)

Sarah Butler¹ and Catherine Lord^{1,2}

¹Center for Autism and the Developing Brain,
New York-Presbyterian Hospital/Westchester
Division, White Plains, NY, USA

²UCLA, Los Angeles, CA, USA

Synonyms

BRS

Description

The Behavior Rating Scale (BRS) is a subtest within the Bayley Scales of Infants Development, which is an assessment frequently used to assess the development of infants and children, including those with a diagnosis of autism. It is a norm-referenced assessment that was first published in 1969 and later revised in 1993 and provides standard mental and motor indices and a developmental age equivalent for children 2 months to 2.5 years old. The Bayley Scales of Infants Development consists of two subtests in addition to the BRS: the mental development index (MDI) and the psychomotor development index (PDI). The BRS is a form for the evaluator to rate the child's behavior throughout testing, including the ability to pay attention, social engagement, affect and emotions, and the quality of movement and motor control. The BRS, previously known as the infant behavior record (IBR), underwent many changes for the second edition, including a revamp in format and a new scoring system.

The examiner completes the BRS after the other two components of the Bayley are assessed (Nellis and Gridley 1994). The examiner also solicits from the parent or caregiver additional information about the tasks and the session as a whole. This includes whether the child's behavior was typical during the session and if the child's performance on the tasks reflected his or her abilities. This information is not included in the BRS

score, but aids in evaluating the accuracy of those scores. The BRS scores can be interpreted at four different levels: total scores, factor scores, item analysis, and comparisons with the other two tests within the Bayley. The total score compares the child with same-aged peers. Factor scores vary depending on age and are described by qualitative labels.

Historical Background

The BRS was previously known as the infant behavior record (IBR) in the original version of the Bayley Scales of Infant Development (Bayley 1969). Since its creation, the Bayley has remained one of the most standardized and widely used measures for determining the developmental skills of infants and children in both clinical and research settings (Wolf and Lozoff 1985; Klin et al. 2005).

Psychometric Data

The Bayley provides a method for obtaining age-equivalent scores for four facets of development, cognitive, language, social, and motor, but empirical evidence for their validity is limited (Bayley 1993). The authors of the Bayley revision (1993) found that the test has excellent statistical properties and sensitivity to high-risk childhood conditions, but its value for assessing young children with autism is limited (Klin et al. 2005). Children with autism typically present with a varied profile of skills, with higher level nonverbal problem-solving abilities, lower level expressive language, and lowest scores in receptive language. Consequently, any composite index score summarizing performance across domains will misrepresent a child's developmental profile, indicating that the actual profile with varied skill levels is more informative than any composite scores.

The BRS contains 30 items that rate the child's relevant test-taking behaviors and simultaneously measures attention/arousal, orientation/engagement, emotional regulation, and motor quality

(Bayley 1993). The scoring of the BRS is based on rank values and has a five-point ordinal scale for each behavior. There is limited psychometric data for the BRS, as most analyses have been completed on the Bayley as a whole. The authors of the revised edition of the Bayley found that total scores were more highly correlated for the older age range ($r = 0.88$) than for the younger age range ($r = 0.70$), but concluded that the interrater reliability for the BRS was fairly high for an observation-based measure (Bayley 1993, as cited in Koseck 1999).

Clinical Uses

The Bayley is particularly relevant in clinical settings with children suspected of having a developmental delay because it can both identify the presence of a developmental delay and provide information to help the caregiver know which services are necessary to help the child (Washington 1998). It is a relevant measure for children demonstrating signs of autism because it tests a wide variety of behaviors across different domains, but it is most informative when the entire profile is assessed, rather than the total scores (Klin et al. 2005). Another reason that the Bayley is frequently used with children with developmental delays is that the testing materials are of interest for these children and can hold their attention (Nellis and Gridley 1994). These qualities of the Bayley and the BRS make the measure highly informative in both clinical and research settings.

Behavior Rehearsal

Rebecca Munday
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Behavior rehearsal involves practicing appropriate behavior responses within social situations. There are many methods for rehearsing social behaviors. One method may include individuals imagining or thinking about themselves performing and responding appropriately to others. A second method may include individuals practicing social interactions through describing them verbally to others. A third method may include role-playing. With all methods, building fluency through repeated rehearsal is vital to achieving success and increasing appropriate social skills.

Description

The Behavior Summarized Evaluation-Revised (BSE-R) is a psychometric instrument designed for research and clinical purposes.

The current version includes 29 items that enable the formalization of behavior observations in the different domains in which specifically autistic difficulties occur.

These domains are touch, eye contact and communication, motor behavior, perception, and imitation. Coding is based on the observations collected by a person who is regularly in touch with the child. The observations are performed in the different situations of daily life by all of the persons who work with the child. A glossary describes briefly the content of each item, which is rated on a 5-point scale ranging from 0 = never to 4 = continuously. The item is rated 0 if the behavior never appears, 1 if it sometimes appears,

2 if often, 3 if very often, and 4 if it is always present. Thus, the total score indicates both the frequency of the behavior disorders and the intensity of the pathology.

Historical Background

Professor Gilbert Lelord and his colleagues designed the first BSE version in 1975 (Laffont et al. 1975). The purpose of this version was to correlate clinical variables with electrophysiological variables. The studies using this scale have demonstrated that certain clinical characteristic such as indifference to others or resistance to change was related to electrophysiological signs such as the low amplitude of the potentials elicited in response to sensory stimuli. The major interest of this technique is to provide a framework for observations that can be repeated in different contexts and at different times in the child's development.

Later, several successive versions involving a varying number of items were developed. The factor analysis provided the means for the classification of the test items into categories.

The 1990 version involved 20 items (Barthelemy et al. 1990). Nine items were later added to the revised version (Barthelemy et al. 1997). A specific version has been developed for infancy and preschool years based on the BSE, and 13 items have been added to describe early manifestations of autism (The infant BSE: IBSE, Adrien et al. 1992).

Psychometric Data

The BSE-R has been validated in a research led by Catherine Barthelemy and her colleagues (Barthelemy et al. 1997); 136 children with autism were included in this study.

Inter-rater Reliability

For the inter-rater reliability study, 29 children (21 boys and 8 girls) were observed and their behaviors assessed with the BSE by two separate groups of nurses trained to use the instrument. The

total score reliability was very high (0.97). Reliability measures were calculated for each item. Three items (1, 10, 29) also had high reliability (0.75–1.0); ten items (2, 4, 5, 6, 9, 12, 14, 20, 27, 28) had good reliability (0.60–0.74); and 12 items (3, 7, 8, 11, 13, 15, 16, 19, 21, 23, 24, 26) had fair reliability (0.40–0.59). Only four items (17, 18, 22, 25) had a low reliability and were therefore excluded from the other analyses.

A factor analysis was performed on the BSE-R results for the 136 children. Six factors were extracted. Two factors accounted for more than 10% of the total variance. Combined, they accounted for a total of 48, 6% of the total variance. The two most loaded factors were labeled “interaction disorder” (items 1, 2, 3, 4, 5, 6, 8, 9, 12, 23, 24, 26, 28) and “modulation disorder” (item 11, 13, 16). A negative correlation was found between the BSE-R score for Factor 1 and Development Quotient. This means that the higher the BSE-R score, the lower the DQ was. No correlation was found for Factor 2 and the DQ.

A criterion validity study was performed on the BSE-R scores for all 136 children. The external criterion was the Expert Severity Score (ESS). This was based on the observation of two experienced staff psychiatrists who were blind to the BSE-R score. The ESS ranged from 1 (minimum) to 5 (maximum). A glossary was available, and for that reason, the ESS had an excellent reliability. Three diagnostic groups were constituted: Autistic Disorders (AD), Pervasive Developmental Disorders Not Otherwise Specified (PDDNOS), and Mental Retardation (MR). A solid relation between the BSE-R score and the ESS was found. Because BSE-R Factor 1 items significantly correlated with the DQ, the variance explained by the DQ was controlled. Each BSE-R Factor Item and BSE Factor 1 score correlated with the ESS. However, the ESS did not correlate with Factor 2 of the BSE-R.

Convergent Validity Study

Seventy-five children were assessed with the Rimland E2 scale. The same subgroups were selected (AD = 51 children; PSSNOS = 8 children; MR = 16 children). Significant differences existed between the three diagnostic subgroups

for the ESS. Correlations were calculated between the BSE-R score for Factor 1, Factor 2, and Rimland E2 score. A significant correlation was found between the BSE-R score for Factor 1 and the Rimland score (0.41). But there was no significant correlation between the BSE-R score for Factor 2 and the Rimland score. Convergent validity was also confirmed in the study by Oneal et al. (2006), where the BSE scores correlated highly with the CARS, a well-validated instrument.

Sensitivity and Specificity Study

Thanks to a ROC analysis, a cutoff of 27 was determined. This score permits a discrimination between autistic children (AD) and nonautistic children (MR + PDDNOS) with a sensitivity of 0.74 and a specificity of 0.71.

Other previously published results concern the first version of the BSE and can be found in different papers (Barthelemy et al. 1990; Reeb et al. 2009).

Recently, a validation study of this scale was carried out in a Lebanese population (Hreich et al. 2016). The scale was first translated into Arabic, and then a back translation was performed. Hundred children with ASD (age range, 35–153 months; DS, 28.0) were evaluated. Their diagnosis was based on DSM4 criteria. The severity of their disorders was measured with CARS. Fifty-eight percent of them had an intellectual disability. Inter-rater fidelity was excellent. The study of internal validity revealed a main factor related to the severity of autistic symptoms (internal consistency of 0.91 in a one-to-one setting and 0.92 in group settings). The external validity was evaluated by the correlation with the CARS score. This study confirmed that the main factor is essentially determined by ASD severity, not by the severity of ID. This factor was named “relational deficiency” according to the initial paper of Barthélémy et al. (1997). In this paper, it is confirmed that BSE-R in Arabic is a practical tool, useful to all team members working with ASD children in Lebanon and the Arab countries. It also allows future research based on reliable tools at an international level.

Clinical Uses

As already indicated, the BSE-R was designed for research and clinical purposes. As the validity and stability of the results obtained with the BSE-R were confirmed, several studies using this instrument were led mainly by Catherine Barthelemy's team.

Biological Measures

Initially, research studies were conducted using the first version (BSE). The objective was to evaluate the severity of behavioral problems in autistic children and to assess the correlations with biological markers. Hameury et al. (1995) using the BSE and other measures distinguished four groups in a population of 202 subjects. Group 1 included subjects with severe autistic behavior, profound mental retardation, and severe neurological symptoms. Group 2 included subjects presenting autistic behavior, language, and communication disorders, with slight or moderate intellectual impairment and mild neurological symptoms. Group 3 included children with severe intellectual impairment and neurological symptoms with no or few autistic behavior patterns. In Group 4, subjects showed multiple but mild disorders. The biochemical parameters of the four groups were compared. The levels of HVA (homovanillic acid) measured in urine samples varied significantly, and Group 3 presented a very high level of HVA compared to the other groups. The authors declare that this approach could make possible the establishment of subgroups in which behavioral clinical profiles could correspond to certain biological profiles (with metabolic characteristics).

Other studies have been undertaken with the BSE revised version. Roux et al. (1997) examined relations between electrophysiological reactivity and BSE-R. In a population of 73 children, they showed that the item "bizarre responses to auditory stimuli" was correlated with abnormalities in frontocentroparietal electrophysiological reactivity, and that the item "unstable attention or easily distracted" corresponded to abnormalities in frontal electrophysiological reactivity.

Hérault et al. (1996) also used the BSE-R in a study on urinary levels of serotonin. No

relationship was found between molecular biology results and clinical scores.

Bruneau et al. (2003) studied relations between late auditory-evoked potentials recorded in the temporal area and autism severity based on BSE-R. They observed a negative correlation between the importance of the right temporal response and the BSE-R score. The greater amplitude of the right temporal responses corresponded to lower (less severe) BSE-R scores on items involving verbal and nonverbal communication skills.

Gomot et al. (2011) examined neural basis of auditory change-detection in children with autism spectrum disorders ($N = 27$) through electrophysiological patterns (MMN, P3a). They wanted to test whether these electrophysiological patterns were quantitatively related to intolerance of change (using the BSE-R scale). Children with ASD displayed significantly shorter MMN latency and larger P3a than controls, indicating a greater tendency to switch attention to deviant events. These electrophysiological abnormalities were significantly more marked in children with greater difficulties in tolerating change. It is therefore confirmed that there is a relationship between the electrophysiological patterns of auditory change-detection and the clinical signs of intolerance to change.

Guimard-Brunault et al. (2013) used eye tracking to compare spontaneous visual attention to a screen displaying a face or an object between children with autism and controls. This study was carried out in a nonconstraint condition. The visual exploration time was measured during passive viewing of static images of faces or objects. The assessment of subjects with autism was conducted with the CARS and the BSE-R. In children with autism, time exploring face screen and time exploring object screen were lower than in control subjects. They were not correlated with intensity of distractibility. No interaction was found between group and type of image on time spent exploring screen. Only time spent in exploring face was correlated with autism symptom severity and gaze impairment.

As the BSE-R is included in the routine assessment of patients in Tours Child Psychiatry Unit, clinical data gathered are available for other

studies in different fields such as genetics (Mbarek et al. 1999).

Sensitivity to Treatment Effects

The BSE and later the BSE-R have been used to evaluate the evolution of children receiving different kinds of treatment. In a study published in 1989, Barthelemy et al. examined the modifications in the BSE scores of 27 children receiving exchange and development therapy over a period of 1–2 years. Different diagnostic subgroups were included (autism, mental retardation, atypical pervasive developmental disorder, developmental delay without autism). The pre- and post-mean BSE scores were compared. The decrease in the scores is interpreted as an improvement. In another study, Barthelemy et al. (1989) assessed changes in BSE scores and biochemical markers in 13 children with autism receiving medication. Significant decreases were observed in a BSE item in responders who also showed significant modifications in serotonin and dopamine levels (Barthelemy et al. 1997). In this study, the treatment lasted 9 months. A significant decrease in BSE-R scores was noted. Other studies (Lelord et al. 1981; Martineau et al. 1988) were led with the BSE as an indicator of improvement. These trials are summarized in Reeb et al. (2009).

In a study carried out by Blanc et al. in 2013, changes induced by EDT (behavior, development, and functioning) were measured at follow-up using the BSE-R among other tools. Thirty-five children with a severe autism associated with a developmental delay followed for 9 months showed improvement in the capacity of exchange and communication.

All these studies suggest that the BSE and the BSE-R are sensitive to treatment effects. However, the number of children included in these trials was usually small and there was no control group. Thus, all these results must be considered with caution.

Family Home Movies: Early Signs

The IBSE has been used in research on early signs based upon family home movies (Adrien et al. 1993). The family movies of 12 autistic children and 12 typically developing children were

analyzed using the IBSE. Two diagnostic-blind raters scored the films. The order of presentation of the videotapes was randomized. The scoring was performed for two different periods, the first and second year, in order to compare the signs observed during these two periods. The analysis of these family movies led to finding specific behaviors that enabled the prediction of the autism diagnosis.

Parents' Rating of Improvement

The BSE is a simple, easy-to-manage tool that has been used for the assessment of improvement by the parents themselves (Oneal et al. 2006). The results show that the BSE presents acceptable psychometric qualities for parent usage when assessing changes in the child's behavior.

The BSE-R is an interesting instrument. It has been validated and can be used in different contexts by professionals from different fields as well as by parents. It can be useful to identify the symptoms of autism, to follow the changes in the expression of these symptoms across age, and to measure the effects of treatment.

Behavior Therapy

Michael D. Powers

The Center for Children With Special Needs,
Glastonbury, CT, USA

Definition

Behavior therapy (a term used here interchangeably with behavior modification) is the application of techniques based on empirically derived principles of learning theory to the treatment of human problems, with the goal of reducing or eliminating unwanted behavior and replacing it with behavior that is more adaptive and socially appropriate. While individual strands of behavior therapy differ in several important ways, all share an emphasis on treating behavioral symptoms, with little or no reliance or attention to underlying unconscious processes. With respect to cognitions, behavior therapy proposes that by changing overt behavior (through reinforcement, extinction, punishment, etc.), more adaptive emotional and affective thinking will follow. The understanding of the “here-and-now” in context, rather

than underlying conflicts in a person's past, is a key distinction between behavior therapy and other more psychodynamic or psychoanalytic therapies.

Historical Background

Behavior therapy has evolved over the past six decades from many schools of thought and philosophical systems. This diversity is most evident in the fact that despite the predominance of the discipline of psychology among practitioners of behavior therapy, some of the earliest pioneers were from other fields, for example, the Russian physiologist Ivan Pavlov and the South African psychiatrist Joseph Wolpe. Equally important is the observation that what we today consider behavior therapy generated from the confluence of the work of three groups in different countries. In the United States, the work of Skinner, Lindsley, and others on operant conditioning adopted a more functional approach to assessment and treatment and led to an emphasis on the experimental analysis of behavior best represented in the field of applied behavior analysis. British psychologist Hans Eysenck and his colleagues at the Maudsley Hospital in London emphasized that behavior problems were the result of complex interactions between the client's personality features, the behavior itself, and the environment. Their work targeted these interrelationships through the use of techniques of behavior change based on S-R learning theory (classical conditioning) as an alternative to the then-prevalent psychoanalytic models. In South Africa, Joseph Wolpe, Arnold Lazarus, and others were at work developing techniques that used behavioral principles to treat more common psychological problems, leading to the development of systematic desensitization and psychotherapy by reciprocal inhibition. At the time, these evidence-based procedures were considered both revolutionary and evolutionary and set the stage for the

continuing development of behavior therapy as a scientific discipline with people with a wide range of psychological problems.

Current Knowledge

Contemporary behavior therapy may arbitrarily but conveniently be classified under five broad strands: applied behavior analysis, neo-behavioristic mediational S-R models, social learning approaches, cognitive therapy and cognitive behavior therapy, and "third-generation" approaches. By far, the most widely practiced with respect to understanding and treating autism are those based on applied behavior analysis (ABA). Here, the extension of the work of Skinner and his early colleagues to Donald Baer, Sidney Bijou, Fred Keller, Brian Iwata, and many others has generated a powerful evidence-based technology of change designed to address significant deficiencies in learning as well as behavioral excesses and deficits exhibited by those with ASD. The cornerstone of ABA is function-based assessment and treatment, with data-based decision-making utilizing a variety of methods. Treatment procedures are designed to modify the relationships between antecedent and consequent stimuli that exert influence or control on overt behavior. There is a clear emphasis on what can be observed and measured; cognitive processes and other private events are typically regarded as beyond the domain of scientific analysis. Because ABA directs itself toward the intensive study of the individual, a wide array of intervention and evaluation strategies have been developed and validated scientifically (see Cooper et al. 2020, for a comprehensive review).

Neobehavioristic mediational S-R models derive from classical conditioning and are most frequently associated with the work of Pavlov, Hull, Mowrer, and Miller. In these therapeutic models, hypothetical constructs (e.g., anxiety) are considered to be mediated by cognitive processes, and treatment techniques are designed to put those processes on extinction, resulting in

behavior change. Systematic desensitization is a procedure most commonly associated with this strand of behavior therapy and is used to effectively treat phobias, fears, and other behavioral responses that are triggered by heightened arousal. Social learning approaches are based on the work of Albert Bandura and his colleagues. These approaches, like other behavior therapies, postulate that behavior is controlled by external reinforcement, external stimulus events, and cognitive mediational processes. Importantly, the cognitive mediational processes determine which environmental influences are more or less valued and receive more or less attention. Because the emphasis in social learning theory is on the individual as the agent of change, self-control, self-management, and self-instruction are prominent parts of the treatment plan. Within this paradigm, operant conditioning and especially modeling are more prominent than classical conditioning, although all are considered.

Cognitive behavior therapy (CBT) and cognitive therapy have become among the most prominent and visible of behavior therapy strands, along with applied behavior analysis, over the past 25 years. These approaches are based on the early work of Arnold Lazarus (multimodal therapy), Albert Ellis (rational emotive therapy), and Aaron Beck (cognitive therapy for depression). All share certain core features with contemporary cognitive models, including the understanding that in order to change behavioral responses, one must also alter the prominence or value of the cognitions or thoughts that accompany the response. CBT seeks to develop retrievable memories of more adaptive responses that will then compete with and replace learned problematic responses by suppressing the memory of those responses (Wood et al. 2011). This is achieved through a talk-based therapy process whereby psychoeducation, teaching coping skills, and in vivo exposure are combined to produce specific skills for change, alternative and more adaptive cognitions regarding change, and actual situations in which to practice change. CBT fosters change in behavior by identifying and challenging

irrational beliefs and misinterpretation of events that cause distress (and maladaptive behavioral responses). CBT has been used with individuals with ASD exhibiting anxiety disorders (Chalfant et al. 2007; Sofronoff et al. 2005), anger management problems (Sofronoff et al. 2007), and disruptive behavior (Solomon et al. 2008; Wymbs et al. 2005) as well as for treatment of core social symptoms of ASD (Wood et al. 2009).

The final strand is both a combination of evidence-based treatments and a reaction to earlier iterations of cognitive behavioral models. These so-called third-generation approaches incorporate a broad array of specific procedures, including dialectical behavior therapy (Linehan 1993), functional analytic psychotherapy (Kohlenberg and Tsai 1991), and acceptance and commitment therapy (Hayes et al. 2012). All share the distinction of a general move away from a more cognitive approach and toward a more functional analytic model of assessment and treatment. In many ways, this return to the basics of behavior therapy is consistent with the core features described by Kazdin (1978), namely, that behavior therapists share a common set of assumptions including a focus on current rather than historical determinants of behavior, an emphasis on overt behavior change as the main criterion by which treatment is to be evaluated, specification of dependent variables and treatment parameters in objective terms so that replication is possible, an emphasis on the bilateral relationship between behavior and the environment, a reliance on basic research methods in psychology as a source of hypotheses about treatment and specific therapeutic techniques, and specificity in definition, treatment, and measuring target populations.

Behavioral Artistry: The Relationship Between Interpersonal Skills and Effective Treatment Repertoires of Applied Behavior Analysis Practitioners

Kevin Callahan¹ and Richard M. Foxx²

¹University of North Texas, Kristin Farmer Autism Center, Denton, TX, USA

²University of Pennsylvania, Harrisburg, PA, USA

Definition

Behavioral Artistry is a repertoire of humanistic, interpersonal behaviors associated with the effective delivery of applied behavior analysis treatment in autism.

Historical Background

In a discussion summarizing 25 years of lessons learned in the development and application of applied behavior analysis practices, Richard Foxx (1998) highlighted a concept from an earlier paper (Foxx 1985) wherein he concluded that the effectiveness of ABA may be negatively impacted by a broad array of deficits in the behavioral repertoires of practitioners. Foxx asserted that there can be important differences in the outcomes achieved by interventionists delivering ABA services in a strictly traditional way (referred to by Foxx as “behavioral technologists”) and those who demonstrate important humanistic, interpersonal behaviors. He observed that some therapists, including individuals with little or no formal behavior analytic training, appear qualitatively better at changing behaviors than their peers with equivalent or even greater levels of training. Foxx described these therapists as “Behavioral Artists” (Foxx 1998, p. 14). Behavioral technologists, according to Foxx, often appear to be practitioners who simply learn a set of scripted,

Behavioral Approaches

► Didactic Approaches

manualized strategies, methods, and procedures and deliver them without much focus on the overall quality of the therapeutic interaction. In contrast to technologists, Behavioral Artists are described as “natural behavior analysts” who demonstrate a set of seven interpersonal characteristics, as well as effective communication skills (Foxy 1998, p. 14).

Foxy hypothesized that there are foundational therapeutic relationship skills associated with the demonstration of “Behavioral Artistry” (BA), including:

- Likes people: Is able to establish rapport; demonstrates concern; wants to facilitate positive change
- Has “perceptive sensitivity”: Pays careful attention to important indicators of client behavior that may be small, subtle, and gradual
- Doesn’t like to fail: Sees difficult clients as a personal challenge to overcome and as an opportunity for the client to succeed
- Has a sense of humor: Recognizes and accepts that much in the educational and human services professions is bizarre, illogical, and humorous
- Looks “for the pony”: Is optimistic and sees behavior change in a “glass half-full” context; always believes programming will be successful; is less likely to burn out
- Is thick-skinned: Doesn’t take negative client actions toward herself or himself personally; maintains objectivity and positivity
- Is “self-actualized”: Does whatever is necessary and appropriate to facilitate and produce positive behavior change; is not under audience control; is creative (Foxy 1985, 1998)

Several of Foxy’s BA components are similar to therapist skills in clinical psychology and counseling and have long been associated with psychodynamic and humanistic/experiential approaches to behavior change. For example, the concept of therapeutic alliance (TA) refers to the collaborative, caring partnership that characterizes a positive client-therapist relationship (Lejuez et al. 2006). TA is seen as a fundamental component of effectiveness within

other therapeutic approaches and has been demonstrated to be a significant predictor of treatment success (Holmqvist 2013; Horvath et al. 2011). Kerns et al. (2018) concluded that a strong therapeutic alliance was related to more positive treatment outcomes in high-functioning children with autism. Similarly, the related concepts of “empathic teaching” in special education (Morgan 1991) and “rapport building” (Shireman et al. 2016) and “compassionate care” (Taylor et al. 2018) in behavior analytic treatment have been highlighted in efficacy literature as essential repertoires among service providers for individuals with disabilities. The influence of empathy, in particular, has been frequently reported within medical and clinical care studies to be a key determinant of positive patient-client relationships and outcomes (e.g., Riess et al. 2012). Nevertheless, the roles and possible significance of these kinds of therapist behaviors in ABA have not been fully explored.

In 2016 Leaf et al. published a review of the skills needed for ABA practitioners to conduct effective programming for individuals with ASD. The authors identified intervention components related to what they describe as a “progressive” and “responsive” approach to the delivery of ABA services. These skills highlight interventionists’ abilities to be flexible and analytical in the implementation of individualized protocols and practices (e.g., while using established EBPs such as discrete trial training and functional analysis) rather than strictly adhering to today’s frequently observed “recipe-based” ABA approach (Leaf et al. 2016, p. 721). Echoing some of the conclusions of Foxy’s research, Leaf and colleagues suggested that the pervasive use of ABA in autism treatment has resulted in changes in its scope and focus, and behavioral interventions have become potentially less effective:

A danger inherent in any large scale, quickly growing area is a loss of focus on meaningful purpose, process, and outcomes. In the field of ABA, this might translate into dogmatic lack of attention to clinical significance, selection of impractical procedures, ritualistic data-collection, over-abundant use of off-putting, dehumanizing terminology, disregard of logistical realities, and insensitivity to consumer issues. (Leaf et al. 2016, p. 728)

Eikeseth (2010) also investigated specific knowledge and skill components necessary to become a technically “competent” provider of early intensive behavioral interventions (EIBI) for children with autism, providing recommendations for assessing and training interventionist skills in the areas of basic intervention, comprehensive curriculum programming, working with families, and supervision. Eikeseth concluded that ineffective EIBI programming is related, in part, to deficiencies in meeting standards of overall program quality: “Highly intensive teaching and supervision will not produce optimal gains if teachers and/or supervisors do not have the necessary qualifications” (Eikeseth 2010, p. 243).

To a large extent, Foxx and other researchers have called attention to the critical need to assess the essential technical skills and related interpersonal characteristics of the individuals delivering ABA services, in order to ensure the future application of ABA as a highly effective and viable treatment approach for persons with ASD. It is possible that the repertoires associated with BA can contribute to sustained improvements in the effective delivery of ABA for individuals with autism and other disabilities.

Current Knowledge

Callahan and colleagues (Callahan et al. 2019) conducted a study to determine if the concept of Behavioral Artistry could be validated and reliably measured using standardized assessments and to determine whether individuals studying and/or working in the field of applied behavior analysis differ from those in other human services professions on important interpersonal skills potentially related to therapeutic effectiveness in autism treatment. In addition, because of the importance of social validity in the selection and effective use of evidence-based treatments in autism (Callahan et al. 2008), these researchers investigated the social validity of characteristics associated with the concept of Behavioral Artistry among the parents of children with ASD. Importantly, Callahan et al. (2019) also assessed preliminary data to determine if there

are differences in the quality of ABA treatment delivered by autism interventionists who have high or low levels of Behavioral Artistry characteristics.

Callahan et al. (2019) determined that the Sixteen Personality Factor Fifth Edition Questionnaire (16PF) instrument could reliably measure Behavioral Artistry characteristics. The 16PF was developed by Raymond B. Cattell in 1949 and is currently in its fifth revision as a widely researched and used, comprehensive, self-report measure of normal adult personality (Institute for Personality and Ability Testing [IPAT] 2009). Designed for individuals aged 16 years and older, the 16PF has been implemented in a variety of research and applied settings (including clinical, counseling, and educational contexts) and has been used to determine and predict levels of creativity, leadership, interpersonal skills, and occupational profiles. The validity and reliability of the 16PF instrument have been well established in more than 4,000 research publications during the past 60 plus years (IPAT 2009). The fifth edition of the 16PF contains 185 multiple-choice items asking simple questions about the respondent’s daily behavior, interests, and opinions. Examples of questions include: “I’d enjoy more being a counselor than an architect (true; false),” and “I believe more in ____ (being properly serious in everyday life; the saying ‘laugh and be merry’ most of the time).” Each question has two narrative choices (“a” or “c”) as well as a “b” choice indicated by a question mark (“?”). Respondents are encouraged to choose the “b” (“?”) response only when neither of the other choices was a better descriptor and are informed that there are no “right” or “wrong” answers.

Responses of the 16PF result in scores on 16 primary personality factors along a bipolar continuum (i.e., each personality factor is represented by two discrete poles, each having a unique, meaningful definition representing a different behavioral profile). For example, on the 16PF personality factor of “Warmth,” respondents could score as being closer to the pole “Reserved, impersonal, distant” or the pole “Warm, outgoing, attentive to others” (IPAT 2009, p. 24).

Using a combination of factor examination, model comparison, and model modification techniques, Callahan et al. determined that eight of the 16PF personality factors are clearly supportive of the BA concept (the factor of “Reasoning,” considered by the test designers to be a brief indicator of intelligence, was omitted from consideration as being largely unrelated to effective ABA intervention). As a result of this statistical modeling, a behavioral artist was hypothesized to represent interpersonal and therapeutic behaviors associated with warmth, emotional stability, liveliness, social boldness, self-assurance, openness to change, self-reliance, and perfectionism.

In order to determine if there was a difference in the level of BA characteristics among university students majoring in ABA and other major areas of study, Callahan et al. conducted an online survey using the 16PF. Undergraduate and graduate students in the majors of ABA, special education, rehabilitation counseling, and other human services majors completed the survey. “Other human services” majors included students in speech and hearing sciences, clinical counseling, psychology, child development, occupational therapy, adapted physical education, and similar majors. Additionally, engineering and computer science students served as a comparison group of persons not expected to pursue professional careers working in human services with individuals with autism or intellectual disabilities.

The 16PF survey results for each respondent were analyzed. For each personality factor, the respondent’s scores indicated whether he or she fell into the BA-compatible pole or the non-BA-compatible pole category. Overall percentages of BA-compatible characteristics were then computed for each respondent. Mean percentages were computed for three main survey respondent groups: (1) Autism Center Group (respondents who were employed part-time or full-time at a university-based autism center delivering ABA therapy); (2) External Group (student respondents not working at the autism center; and (3) Combined Group (all respondents, including undergraduate and graduate students working at the autism center and students external to the autism center).

Finally, Callahan et al. conducted observations of ABA therapists to determine if those with the highest and lowest percentages of BA characteristics looked qualitatively different in their delivery of ABA therapy. The research team posited that therapist behaviors associated with the Foxx BA characteristics “Likes People,” “Thick-Skinned,” “Perceptive Sensitivity,” and “Sense of Humor” could be observed during the delivery of typical discrete trial training (DTT) and naturalistic environment teaching (NET) programming. Operational definitions for each of these BA characteristics were developed. However, during field testing it became apparent that only behaviors associated with “Likes People” occurred frequently enough during therapy sessions to measure meaningfully as a component of BA. It was further observed that behaviors associated with the Foxx characteristics of Thick-Skinned and Sense of Humor were subsumed within the definition of “Likes People.”

“Likes People” was generally defined as observable demonstrations of enjoyment and concern directed toward a client, with four associated behavioral indicators: (a) pleasant facial expression; (b) positive tone of voice; (c) sustained gaze at the client; and (d) body proximity and orientation toward the client. “Likes People” could only be scored during times the therapist was engaged in social interactions with clear communicative and therapeutic intent. The occurrence or nonoccurrence of the four indicators of “Likes People” was scored by data collectors using a partial interval data sheet, on which a 10-minute observation period was divided into 10-second scoring intervals. If the behavioral indicator was observed at any time during an interval, data collectors marked a “+” on the data sheet. A total percentage of occurrence was computed for each of the four behavioral indicators for each observation session. Data collectors were required to demonstrate mastery of the scoring system before beginning BA scoring.

In addition to partial interval scoring of the behavioral indicators of “Likes People,” data collectors recorded a subjective rating of the

therapist's behavior throughout the entire 10-minute therapy session, based on a standardized description of typical examples of the target behavior, as follows: "Likes People will typically appear as a person who is fun, friendly, and child-like; energetic, positive, and affectively expressive; uses appropriate physical touch and gestures; appears attentively interested in what the client is doing; is engaged in activities that demonstrate care for the client's welfare and happiness; demonstrates empathy, respect, and politeness." At the conclusion of a scoring session, data collectors subjectively rated the therapist's "Likes People" behaviors. Behavioral technologist behaviors related to the fidelity of implementation of ABA were also assessed.

The results of the Callahan et al. (2019) study indicate that students majoring in ABA had the lowest overall levels of BA characteristics across all human services majors. Notably, the personality factors of "warmth" and "perfectionism" were significantly lower among ABA majors. Parents of children with autism rated descriptors of BA behaviors as significantly more preferable than non-BA behaviors for the therapists working with their children, providing an indicator of social validation for the concept of Behavioral Artistry by this important consumer group of autism treatments. Importantly, therapists with higher percentages of BA characteristics were rated as delivering higher-quality ABA, including both BA ("Likes People") and behavioral technologist therapeutic behaviors.

Future Directions

Callahan et al. (2019) concluded that the effective practice of ABA for individuals with ASD can be broadened and improved by incorporating BA repertoires into the ongoing delivery of treatment. While acknowledging the preliminary nature and limitations of their research, they identified several key directions for future research. Addressing each of the four questions below will be of paramount importance in further validating the potential impact of BA on the fields of ABA and autism treatment.

1. What are the relationships between the technology and artistry of ABA treatment in autism? For the past several decades, the literature on ABA programming for children with autism has focused almost exclusively on improving the *technology* of treatment. Researchers and practitioners have done an exemplary job identifying evidence-based practices (EBPs) and developing curricula to increase effective autism programming. Indeed, Foxx's seminal articles which introduced the concept of Behavioral Artistry (Foxx 1985, 1998) also included robust emphases on the necessary technological knowledge and skills therapists must possess in order to be effective providers of ABA treatments. In the Callahan et al. (2019) study, therapists with both the highest and lowest levels of Behavioral Artistry demonstrated relatively similar levels of technical competence. Thus, one may conclude that most ABA practitioners, if adequately trained and supervised, can deliver ABA protocols with technological fidelity. However, it can be argued that the repertoires of behavioral technologists, although necessary, are not sufficient to continue to advance the development of the fields of behavior analysis and autism treatment in order to attain maximum, broad-reaching clinical and educational impacts. Researchers must continue to examine the qualities and corresponding behaviors of exemplary behavior analysts, including identifying how components of humanistic therapeutic care may be integrated within the delivery of high-quality ABA treatment. As Taylor et al. (2018) point out, the empirically derived *technical skills* of behavior analysts will always remain a critically important component of client outcomes. Nevertheless, "those methods do not exist separately from relationships with clients and their caregivers" (Taylor et al. 2018, p. 1). Future research should investigate these relationships, and the potential synergies that could result from maximizing technical competence *in coordination with* Behavioral Artistry repertoires. Such research could prove to be a valuable addition

- to the literature on the relationship between therapist interpersonal skills and effective practice (e.g., Anderson et al. 2009; Keijsers et al. 2000; Lambert and Barley 2001).
2. Can the repertoires of Behavioral Artistry be effectively trained? Another important focus for future research is to determine if autism practitioners with lower levels of BA can be taught to consistently demonstrate associated behaviors at a higher level. In addition to recent efforts within the field of ABA (e.g., Lugo et al. 2017; Shireman et al. 2016), other helping professions, such as counseling, have also concluded that the basic skills of establishing therapeutic rapport are, indeed, trainable (Carkhuff 2009; Lambert and Barley 2001). It is possible that by using ABA-based training methods such as Behavioral Skills Training (e.g., Parsons et al. 2012), novice therapists can be taught to recognize skill deficits and receive effective training to remediate them. Crucial additional questions will include how much improvement can be achieved and whether or not the observed changes are clinically significant and appear genuine.
 3. Do the behavioral repertoires associated with Behavioral Artistry improve student/client outcomes? It is important for researchers to demonstrate that the implementation of BA skills results in greater school and life outcomes. Hypothetically and logically, ABA therapists who are warm, attentive, creative, optimistic, and persevering should engage clients instructionally at higher levels and minimize escape-avoidance and problem behaviors, allowing for the more effective delivery of their corresponding technologist repertoires. Nevertheless, future research should examine the interpersonal characteristics and behaviors of ABA practitioners with the intention of identifying more precisely the repertoires and behaviors associated with the most positive client outcomes. The social validation of these outcomes is vitally important, especially for a field which continues to be subject to negative public perceptions and misperceptions, and less than universal acceptability of its methods and language (Critchfield and Reed 2017; Woolfolk et al. 1977). The parent survey results reported by Callahan et al. (2019) suggest that at least this important consumer group supports the inclusion of the interpersonal aspects of Behavioral Artistry as a future hallmark of ABA therapy in autism intervention.
 4. What can the fields of ABA and autism intervention and education do to identify, recruit, and retain practitioners with positive interpersonal behaviors? Expanding the definition of effective ABA practitioners to include the characteristics of Behavioral Artistry can potentially improve the delivery, outcomes, and acceptability of ABA treatment for individuals with ASD. The preliminary results of Callahan et al. (2019) suggest that persons with the highest levels of Behavioral Artistry may often seek other human services professions than ABA in which to apply their therapeutic skills. It is unclear why the students in that study majoring in ABA had the lowest levels of Behavioral Artistry, and, more concerning, the lowest levels of warmth, across all groups of human services providers. However, this is a compelling finding. It could be beneficial for the field of ABA to conduct a large-scale self-study effort to investigate this phenomenon.

Behavioral Assessment

Michael D. Powers

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Behavioral assessment is the process of objectively identifying and evaluating units of response (behaviors) and related controlling environmental and organismic variables so that specific behaviors can be better understood and changed (Cooper et al. 2020; Nelson and Hayes 1979). It is pragmatic in nature, in that behavioral assessment seeks to determine and describe underlying functional relationships between behavior and the person in their environment and then uses

that understanding to facilitate the development of new, more adaptive functional responses. By emphasizing objective identification and measurement of environmental and organismic-dependent variables that may influence behavior, behavioral assessment ultimately serves treatment planning and outcome evaluation.

Historical Background

Behavioral assessment has a long past but a relatively short history. With the advent of behavioral approaches to understanding and treating individuals with varying problems (e.g., fears and phobias, depression, anxiety, self-injurious behavior) over the past 60 plus years, behavioral assessment had been somewhat of an informal process until the 1970s when closer attention to those dependent variables that contributed to behavioral treatment success or failure began to receive greater attention from researchers and clinicians. As would be expected, there was an initial emphasis on what behavioral assessment *was not* and in specifying differences between behavioral and so-called traditional or psychodynamic assessment. Those differences were succinctly summarized by Mash (1979), who noted that at a conceptual and applied level, behavioral assessment is characterized by the view that human behavior is predominantly under the control of environmental and organismic events, rather than underlying intrapsychic processes, introspection, or personality traits that are inferred. Further, behavior must be examined in context. While these were radical ideas at the time, particularly as regards the treatment of mood, developmental, and conduct disorders of adults and children, this approach was prescient. As the relationship between brain and behavior is better understood through sophisticated neuroimaging techniques and through advances in neurobiology, genetics, and neurochemistry, it becomes clear that context is everything. These variables, once broadly called *organismic*, now are more precisely described and differentiated. The result is that behavioral assessment procedures are now

better able to help pinpoint functional relationships so that treatment selection and efficacy improve, with greater generalizability beyond the treatment setting.

In practical terms, behavioral assessment evolved initially after behavioral treatments were devised, rather than before it. While this observation helps to understand the recency of more sophisticated assessment strategies, it also provides a context for understanding why so many behavioral interventions for complex psychological disorders have become evidence-based treatments of choice over the past 40 years (e.g., cognitive behavior therapy for individuals with anxiety, depression, and anorexia and bulimia and dialectical behavior therapy for those with borderline personality disorder). Behavioral assessment is rooted in the understanding that behavior must be examined in context, with direct samples taken in multiple settings, utilizing multiple methods of inquiry. With these much more precise, operationalized, and objective formulations, the clinician is able to more accurately specify what is expected or predicted to change and then to evaluate whether change, in fact, occurred after the introduction of treatment. It is this hypothesis-testing process that compliments the rejection of inferred causation and makes the behavioral assessment process inherently objective, dynamic, and responsive to new evidence. Indeed, the reliance on the basics of the scientific method permits the needed flexibility to abandon or modify a treatment approach if it is not working as planned.

Current Knowledge

The technology of behavioral assessment is ever-expanding but is always directed toward understanding behavior functionally (see ► [“Functional Analysis”](#)) through the use of direct and indirect assessment methods. It is important to emphasize, however, that indirect assessment does not imply a reliance on inference. Rather, indirect behavioral assessment methods such as questionnaires (e.g., Questions About Behavioral Function; Paclawsky et al. 2001) and rating scales (Social Responsiveness Scale; Constantino and Gruber

2005) are used in conjunction with direct observation methods to clarify points of behavioral convergence and are themselves designed to measure behaviors that have been more precisely and operationally defined so that interobserver agreement is high.

Identification of target behavior is the first step in a comprehensive behavioral assessment and requires that behavioral form and function be described, including function, topography, duration, frequency, and intensity of the behavior. This is done in such a way that the description becomes an *operational definition*, specifying explicit and precise response parameters. Once completed, determination of controlling variables is undertaken using indirect and direct methods. Indirect methods include third-party interviewing with a structured assessment format such as the functional assessment interview (O'Neill et al. 1990), review of incident reports or permanent products of the behavioral episode, or more informal interviews with parents or caregivers. Direct assessment procedures include direct observation of the target behavior in the natural or analog environment using any number of methods (e.g., momentary time sampling, partial interval recording) as well as descriptive analysis of the behavior using antecedent-behavior-consequence (ABC) analysis. In all cases, the behavioral assessor seeks to describe controlling variables of three types: antecedent stimuli, consequent stimuli, and organismic stimuli. Antecedent stimuli can be discriminative stimuli (they predict the expectation of a particular response because the person has learned that their response is followed by a specific consequence) or elicitors (which evoke automatic, physiological, or emotional responses). These immediate “triggers” help to understand the impact of a particular stimulus event on the person and their behavior.

An assessment of context is undertaken in the form of analysis of setting events and establishing operations. Setting events are variables that influence an ongoing relationship between a stimulus and a response, whereas establishing operations momentarily change the reinforcing value of a discriminative stimulus. There are technical differences between both terms, but both describe antecedent conditions that alter response

probability. For example, when ill or satiated on a specific reinforcing stimulus, a person might respond differently than when healthy or in a deprived state. These are assessed because these variables are more distant from the target behavior (may not occur immediately before the target behavior), but they may persist over time, or exert a cumulative effect, and influence the target behavior. Knowing them highlights a possible point of intervention.

Target behavior can be embedded in a behavioral chain, and assessment for this is important because it may provide an opportunity to intervene at an early point in the chain, thereby interrupting the variables that would normally control the response. Equally important is the assessment of high- and low-probability settings. That is, it is important to understand where and when the target behavior is more or less likely to occur as a method for considering stimulus control.

Behavioral assessment of consequences refers to those stimuli that reliably occur after the target behavior is emitted. These are critical to understand that they represent those contingencies maintaining (reinforcing) the behavior. For behavior change to occur, those contingencies of reinforcement must be modified so that a problematic target behavior is no longer reinforced by the stimulus maintaining it, clearing the way for an alternative, more adaptive response to be reinforced and established to replace the problem behavior.

Organismic stimuli have received somewhat less attention from researchers over the years, but with the advent of more sophisticated technologies (e.g., with neuroimaging or for genetics), a greater emphasis is being placed on the relationship between physical, biological, and neurological status and behavioral expression. For example, identification of lesions in a specific area of the brain (as would occur with tuberous sclerosis) may help the clinician better understand the context for a challenging behavior. This would not necessarily reduce the importance of addressing the target behavior, but it would likely support an interdisciplinary approach to treatment.

Two final areas must be considered in behavioral assessment if the assessment results are to fully inform treatment planning. The first is an assessment of preferences and reinforcers, and

the second is the identification of functionally equivalent behavior(s) that can be taught as a replacement for the target behavior to be reduced or eliminated. There are a number of empirically based strategies for evaluating which stimuli are preferred by a client. They (or caregivers) can be queried, observed, or placed in a formal trial-based assessment environment. An example of the latter is a “forced choice” or paired stimulus presentation whereby two items are presented to a client, all matched randomly. Preferences are determined by frequency of selection of specific items (see Fisher et al. 1992 for an example). In contrast to preferences, reinforcers can only be identified by a functional test. That is, when presented, a stimulus is only considered a reinforcer if it increases the likelihood of reoccurrence of the behavior it followed. There are several ways to conduct a reinforce assessment including those based on concurrent, progressive ratio, or multiple schedules (see Cooper et al. 2020, for examples).

If behavior change is to be achieved, generalized, and maintained, it must gain for the client the same functional outcome, but with greater ease and efficiency, and be more socially desirable and valid than the problem behavior that it replaces. In short, the replacement behavior must work better and faster and be useful and valued in a large number of environments. Determining which behavior to select as the replacement is an essential task in behavioral assessment for several reasons. If left unaddressed, the client may well substitute yet another (and potentially undesirable) behavior in place of the target behavior that has been reduced because the functional need for the behavior still exists. For example, if hitting another person has been a successful means of escaping from a task demand and hitting is reduced without concurrent teaching of a replacement skill that serves the same function, the client may substitute self-injury as a means of escape. If a replacement skill is selected but it is not functionally equivalent, the client will not have an alternative that serves the same functional purpose. In this case, the new skill may be acquired but the target behavior is not reduced. Finally, if the replacement skill to be taught is functionally equivalent, but requires more response effort, or is not reinforced on a sufficiently dense schedule

of reinforcement, then it is less likely to be demonstrated by the client and less likely to serve as a replacement in the long run. In the final analysis, the treatment of behavior problems is better understood as the effective teaching of functionally equivalent, more adaptive replacement skills. This component of the assessment is critical.

The final component of behavioral assessment is a functional demonstration of the relationship between those antecedent, consequent, and organismic variables and the target behavior. This process is termed functional behavior assessment if done without a set of empirical analog conditions and functional analysis if implemented with those analog conditions. Both components are described in detail elsewhere in the *encyclopedia*.

When complete, the behavioral assessment process informs treatment planning and decision-making. In contrast to other, more traditional (and nonbehavioral) assessment approaches, however, behavioral assessment is ongoing. That is, while it does serve a predictive function by helping to elucidate relevant variables that impact the target behavior, it also serves a formative function (informing ongoing decision-making through analysis of treatment effects) as well as a summative function (providing a framework for understanding the target behavior from the point of first identification through resolution and replacement).

Future Directions

If advances in behavioral assessment over the past four decades have emphasized anything, it is that the process is dynamic and data-driven. Whether through the development of more sensitive rating scales for problems experienced by those with ASD or use of microtechnologies to more precisely measure small units of response, the likelihood that future iterations of behavioral assessment will better support treatment planning is without question. Ongoing work in several areas will be especially useful. The continuing analysis of antecedent stimuli, and particularly establishing operations, will continue to support precision intervention. A better understanding of the relationship between information processing

deficits, including those that impact academic performance, will support the development of more sensitive replacement skills that include curriculum modifications and accommodations. Recognizing that exceptional behavioral assessment science and technology is no guarantee that utilization or implementation will proceed correctly, future efforts to better understand the contingencies motivating organizations and systems serving those with ASD will be very valuable.

The availability of sophisticated technologies to objectively evaluate small but significant units of responding in persons presents many exciting opportunities. While the relationship between exciting new findings related to eye gaze in very young infants and toddlers with ASD (Klin et al. 2009) and later social development has yet to translate into intervention protocols demonstrating long-term effects, this area seems one of the top candidates for a marriage of technology with behavioral science. Further, neuroimaging technologies (e.g., fMRI) can map specific brain responses to presented stimuli, and an exciting next step would be to evaluate whether behavioral treatment effects demonstrated through overt behavior lead to discernable change in brain functioning and whether collateral changes are also noted neurologically. Finally, as basic science continues to articulate ways in which those with ASD are (and are not) different from those who are neurotypical, the opportunity for greater interdisciplinary behavioral assessment at the neurological, genetic, and biological levels is exciting. Behavioral assessment is built on the science of specification, not speculation, and good measurement across disciplines has a synergistic effect. The next decades will be exciting ones.

Behavioral Assessment Scale of Oral Functions in Feeding

Stephanie Bendiske
The Center For Children With Special Needs,
Glastonbury, CT, USA

Description

This rating scale assists practitioners to establish a baseline of oral functioning and feeding as well as measure change over time. It should be

utilized in conjunction with an assessment that measures oral structure and muscle tone in children. This scale provides visual feedback of progress as well as assists to plan and justify feeding therapy.

The rating scale includes the following oral motor skills:

- Jaw closure
- Loop closure over a spoon
- Tongue control
- Lip closure while swallowing
- Swallows food without excess loss
- Chews food (tongue/jaw control)
- Sips liquids
- Swallows liquids without excess loss
- Swallows food without coughing

Historical Background

This rating scale was developed by Margret Stratton and published in the *American Journal of Occupational Therapy* in November 1981. The rating scale was developed for people with multiple handicaps and developmental disabilities. Ms. Stratton utilized this rating scale within the J.N. Adam Developmental Center in Perrysburg, New York.

Psychometric Data

This is a criterion-based rating scale. Standard scores are not calculated. The client's oral motor functioning is rated on a scale from 0 to 5 with 5 being normal and 0 being disordered or passive movement.

Behavioral Curricula

Marjorie H. Charlop¹, Benjamin R. Thomas² and Catherine Miltenberger³

¹Claremont McKenna College, Claremont, CA, USA

²Claremont Graduate University, Claremont, CA, USA

³Trumpet Behavioral Health, Lakewood, CO, USA

Definition

Broadly defined, curriculum refers to the content and order of instruction, the instructional strategies used to teach this content, and any assessment or other materials used to implement the educational program (Olley 1999, 2005). Curriculum is also structured by a conceptual framework to guide the treatment model in addressing the core deficits of autism spectrum disorder (ASD) and promoting developmental outcomes (Wong et al. 2015). **Behavioral curricula** are a specific type of curriculum that incorporates behavioral principles (e.g., an emphasis on functional behavior, operationalizing behaviors and objectives, and measuring behavior). Behavioral curricula recognize the importance of individualizing the content, sequence, and method of instruction to best meet each individual's needs (Gould et al. 2011). They also tend to target the reduction and replacement of interfering behaviors (e.g., stereotypic behavior, tantrums; Olley 2005). The characteristics of behavioral curricula are especially appropriate for children with ASD for a couple of reasons. First, behavioral strategies have been found to improve the communication, social, and other skills of children with ASD (Schreibman and Ingersol 2005; Wong et al. 2015). Second, children with ASD differ in their individual strengths and weaknesses and are believed to benefit from individualized educational programs (Olley 1999).

Historical Background

Behavioral treatment approaches are the most common treatment programs for ASD (Weitlauf et al. 2014). Accordingly, recent decades have seen a marked increase in the development of educational curricula for children with ASD (Olley 2005; Wong et al. 2015). Researchers and practitioners have created and evaluated a number of comprehensive and focused (e.g., language, social skills, or academic) curricula (Wong et al. 2015). Many of these have been behaviorally based curricula.

Current Knowledge

Treatment goals for children with ASD include improving social behavior and reducing interfering behavior to increase functional skills, social integration, and independence (Myers and Johnson 2007). Like all curricula, behavioral curricula can use a variety of instructional strategies to target language, social, academic, adaptive, and other skills (Olley 2005). Behavioral curricula incorporate behavioral principles including an emphasis on functional behavior, operationalizing behaviors and objectives, measuring behaviors, individualizing programs to meet each child's needs, and targeting the acquisition of prerequisite skills and the reduction of interfering behaviors. These components are briefly described below.

Functional Behavior

Behavioral curricula focus on functional behaviors. Functional behaviors are behaviors that are useful to the individual. More specifically, behaviors are considered functional if they allow the individual to better navigate his or her current environment, are required to learn or likely to lead to the acquisition of other functional behaviors, increase the individual's ability to navigate other beneficial environments (e.g., general education classrooms), or make others more likely to interact with the individual (e.g., eliminating disruptive or aggressive behaviors may make peers

more willing to initiate interactions with the individual; Cooper et al. 2007). Many individuals with ASD require treatment in numerous areas. Instructors should attempt to identify and target behaviors that are most useful to the individual's current functioning (Cooper et al. 2007). To determine which behaviors would be most useful, instructors should observe the individual in his or her natural environment and include parents and others familiar with the individual (Cooper et al. 2007; Olley 2005).

Operationalizing Behaviors and Objectives

Behavioral curricula emphasize the importance of operationalizing behaviors and objectives. All targeted behaviors should be objectively, clearly, and completely defined. To be objective, the behavior should be described in observable terms. To be clear and complete, the definition should provide comprehensive criteria for behaviors that will be included or excluded (Cooper et al. 2007). Defining targeted behaviors in this way allows teachers and other people working with the individual to count the occurrence of the behaviors and track student progress.

Similarly, behavioral programs operationalize objectives or student goals. For each targeted behavior, there should be specific and objective criterion for mastery (Gould et al. 2011). This criterion should reflect the level of competence that allows the individual to use the behavior to successfully navigate his or her natural environments (Cooper et al. 2007).

Measuring Behavior

Behavioral curricula place a strong emphasis on measuring behavior. Clear and comprehensive operational definitions of targeted behaviors allow teachers and others working with the individual to measure the individual's demonstration of behaviors. An initial measure of the individual's ability allows the instructors to determine his or her current level of ability. Measuring the

targeted behaviors during intervention provides instructors with objective information on student progress (Cooper et al. 2007).

Individualization

Behavioral curricula are usually designed to be individualized and meet each individual's needs (Najdowski et al. 2014; Olley 2005). This may be especially important for individuals with ASD, who share common areas of impairment but demonstrate considerable variability in their abilities and deficits. Measuring the individual's behavior allows instructors to identify that individual's need and focus the curricula accordingly. Regular measurement of the individual's progress provides instructors with information on that individual's response to different instructional strategies. Again, this information can be used to identify instructional strategies that are more effective for that individual student and to update their program content as necessary (Cooper et al. 2007).

Targeting Prerequisite Skills and Interfering Behaviors

Many individuals with ASD lack basic prerequisite skills and demonstrate interfering behaviors. Behavioral curricula tend to target these behaviors early in an individual's program. Prerequisite skills refer to behaviors that facilitate later learning. For example, behavioral programs often target compliance (i.e., following the instructor's instructions), nonverbal and verbal imitation, and attending behaviors (e.g., remaining seated, focusing on presented stimuli; Olley 2005). Consistently demonstrating these and related skills allows the individual to benefit from instruction and facilitates the acquisition of later skills.

Interfering behaviors hinder the individual's ability to learn. These may be inappropriate behaviors, such as stereotypy, aggression, self-injury, or other issues, including sleep disturbances or dietary concerns (Olley 2005). These

and related behaviors and issues affect the individual's ability to participate in and concentrate on instruction. Reducing or eliminating these inappropriate behaviors or concerns increases the individual's ability to focus on and benefit from instruction.

Empirical Support

The components of behavioral curricula are consistent with current best practices for ASD treatment. Existing empirical evidence indicates that effective programs use assessment and progress monitoring to individualize program content and instruction to meet the individual's needs and facilitate his or her independence in his or her natural environments. Therefore, it is recommended that programs for individuals with ASD include these elements (Crimmins et al. 2001; National Research Council 2001; New Jersey Department of Education 2004). Further, there is a large and growing body of research indicating that behavioral strategies can improve the language, social, and other skills of children with ASD. Because behavioral curricula incorporate these components and strategies, there is reason to believe that they may be effective.

However, there is relatively little research examining the effectiveness of curricula content (Olley 1999). More specifically, there is a lack of research examining how specific content and sequence of instruction affect the progress and long-term outcomes of children with ASD. Because of the importance of individualizing each student's program, the necessity of this type of research is unclear (Olley 2005). However, more information could be useful in developing effective programs that best facilitate individual's progress.

Additional research is also needed to validate different behavioral curricula. Researchers and program personnel have conducted studies examining the effects of or outcomes associated with different behavioral curricula (e.g., Arick et al. 2003). However, no single curricula has the empirical support required to meet the criteria for an efficacious treatment (Olley 1999, 2005).

Existing Behavioral Curricula

There are numerous behavioral curricula designed for children with ASD and other disabilities. Three of these are described below. However, these descriptions only provide a brief overview of the program. For more complete information, please refer to the program manuals or other references.

The Early Start Denver Model (ESDM)

The Early Start Denver Model (ESDM; Rogers and Dawson 2010) is a comprehensive and evidence-based behavioral developmental intervention for young children with ASD. Goals of ESDM span all developmental domains with an emphasis on targeting the core deficits of ASD and teaching behaviors in a typical developmental sequence. Research on using the ESDM curriculum and treatment approach has shown gains for young children with ASD in IQ, expressive and receptive language, and social behavior (Dawson et al. 2010). After 1–2 years of treatment, children have also experienced diagnostic shifts toward a milder diagnosis, and electroencephalography (EEG) measures of their engagement and cognitive processing were comparable to typically developing children (Weitlauf et al. 2014).

The structure of ESDM programs is a blend of behavioral, play-based, and relationship-based approaches that are organized by empirical knowledge on child development and ASD. The standardized ESDM curriculum uses the *Early Start Denver Model Curriculum Checklist* assessment to guide individualized behavioral programs. Teaching strategies used are empirically supported methods of applied behavior analysis, and data are used to monitor progress and inform modifications to the program.

There are several core components of ESDM, including a focus on interpersonal interactions and positive affect, reciprocal and functional imitation with facial expressions and objects, shared engagement with joint activities, verbal and non-verbal communication training, and embedding instruction within naturally occurring play and daily routines (Rogers and Dawson 2010).

Each ESDM program has a primary therapist in the home who has ESDM training and holds a certification. Along with a multidisciplinary team, the therapist develops a partnership with parents by teaching strategies to use in the home during daily routines and play (Rogers and Dawson 2010). The ESDM curriculum also offers a companion manual for parents, *An Early Start for Your Child with Autism* (Rogers et al. 2012), that can be used outside of sessions to support the program.

Strategies for Teaching Based on Autism Research (STAR)

The Strategies for Teaching Based on Autism Research (STAR; Arick et al. 2004) program provides instructors with assessment materials, lesson plans, activities, materials, and data collection systems (Arick et al. 2004). The program targets children's receptive, expressive, and spontaneous language; adaptive skills; academics; play; and social skills. These skills are targeted via discrete trial training (DTT), pivotal response training (PRT), and functional routines. All three of these are empirically supported behavioral strategies. The STAR program also recognizes the importance of and provides teachers with strategies for promoting skill integration and generalization.

Research indicates that children with ASD who are exposed to the STAR program do make progress. Special education professionals provided teachers and other staff members with yearly workshops that used the STAR program materials to review DTT, PRT, functional routines, and data collection strategies. Over the next 12–16 months, many of the teachers and staff members' students with ASD demonstrated significant improvement in language, social skills, academics, and autonomy (Arick et al. 2003). Although promising, more research is needed to determine the extent to which the STAR program caused this progress.

The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP)

The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP; Sundberg 2008) includes an assessment, curriculum guide, and

progress monitoring system that are used to develop language programs for young children with ASD and other language delays (Sundberg 2008). The targeted skills, assessment, and curriculum suggestions are derived from B. F. Skinner's work on verbal behavior, developmental research, and empirically based behavioral principles and strategies (Sundberg 2008).

The VB-MAPP is composed of the milestone assessment, the barriers assessment, the transition assessment, task analysis and skills tracking, and placement and IEP goals (Gould et al. 2011). The milestone assessment examines the child's current language and related abilities. The barriers assessment is intended to identify existing interfering behaviors or absent prerequisite skills that could affect the child's ability to learn. The transition assessment evaluates skills that the child needs to transition to and succeed in new and less restrictive environments. The task analysis and skills tracking system operationally defines over 900 skills from the different targeted areas. This can provide more detailed data about the child's initial abilities and progress and guide program development. After assessing the child, instructors can consult the placement and IEP section for recommendations for the child's goals and educational settings.

The VB-MAPP has undergone field testing. However, more research is needed to establish its psychometric properties and examine its effectiveness (Gould et al. 2011).

Future Directions

There has been an increase in the development of and research examining behavioral curricula for children with ASD. However, many of these studies have limited internal validity, small samples, and examine program instruction and content together (Arick et al. 2003; Olley 1999). Future research should address these issues. Longitudinal research should also be used to examine the long-term effectiveness of different programs.

In addition, many of the existing behavioral curricula are designed for young or high-functioning children with ASD. There is a need

to develop empirically supported behavioral curricula for older and low-functioning individuals with ASD (Olley 1999, 2005).

These and related areas of research will provide researchers and practitioners with the information needed to develop effective behavioral curricula for individuals with ASD. This information will also help instructors to select appropriate interventions for individuals with ASD. Doing so will facilitate individuals' progress and promote independent adult outcomes.

Behavioral Development Questionnaire

Anne Snow

Child Study Center, Autism Program, Yale University, New Haven, CT, USA

Synonyms

BDQ; Wing subgroups questionnaire (WSQ)

Description

The Behavioral Development Questionnaire (BDQ) is a measure that assesses several behavioral domains of autism spectrum disorders (ASD) in an attempt to subclassify individuals on the autism spectrum based on their behavioral topography. It is based on the subclassification scheme proposed by Wing and colleagues, which identified the four following ASD subtypes: aloof, passive, active-but-odd, and normal (Wing and Gould 1979, please see section “[Historical Background](#),” below).

The behavioral domains assessed by the BDQ focus on quality of social interaction but also include symbolic play, motor imitation, nonverbal and verbal communication, daily routines, stereotyped behavior, and motor coordination (Castelloe and Dawson 1993). The BDQ consists of 13 groups of four descriptions of behavior, each description corresponding to one of the four ASD subgroups. Parents are asked to rate each description on a 7-point Likert scale with regard to how well it describes their child (0 = never, 6 = always). Additionally, for each group of items, parents are asked to select the one description that best describes their child. Only the item-level ratings are used in scoring the BDQ.

As each description corresponds to a social subtype, the BDQ is scored by summing the ratings for each subtype. Missing items are prorated based on the average score of available items. The child is assigned to the subtype for which he or she received the highest score.

Historical Background

As stated previously, the BDQ is based on the ASD subtyping system developed by Lorna Wing and Judith Gould (1979). Wing and Gould's seminal paper (1979) was an epidemiological study of all children living in Camberwell, London, aged under 15 years who showed ASD-like impairments. The researchers found that the social impairment that characterized this group was expressed in one of four ways. *Social aloofness* was characterized by indifferent social behavior. *Passive interaction* involved the absence of spontaneous approach behavior but the acceptance of approaches made by other children. *Active but odd* interaction included children who spontaneously approached other children but their interactions were one-sided and characterized by repetitive preoccupation with certain phrases or topics of conversation. The fourth group was the *appropriate interaction* subtype, which included children whose social interactions were normal for their level of cognitive development. These groups were proposed to exist on a continuum, with the aloof individuals representing the most severe end of the spectrum of impairment, and the active but odd individuals at the mild end.

It was then hypothesized that individuals with ASD could be subclassified based on these categories of social impairment. Furthermore, Wing proposed that these social classifications would correlate with other patterns of behavior. Indeed, the subtypes were examined and it was found that patterns of behavior tended to occur together. The aloof group comprised the highest proportion of children with autism and was significantly associated with a history of Kanner's (1943) "typical" autism (socially aloof, repetitive routines, speech characterized by reversal of pronouns and idiosyncratic phrases). Patterns of abnormal behavior were also evident between the three groups. Stereotyped and repetitive behavior characterized the aloof group, and repetitive speech and behavior patterns were seen more frequently in the passive and active but odd groups (Wing and Gould 1979).

Since the inception of Wing's subclassification system, it has been accepted by the field as

providing rich clinical descriptions of individuals with ASD (Volkmar and Klin 2005). However, subgroups have largely been assigned based on clinical impression rather than in a systematic fashion. The goal of the BDQ was to create a standardized measure for subclassifying children according to the Wing subtyping system.

Psychometric Data

In the initial study of the BDQ, the questionnaire was completed by parents of children with autism ($n = 34$) or PDD-NOS ($n = 6$) between the ages of 4 and 20 years (Castelloe and Dawson 1993). Separately, clinicians assigned the children to a Wing subtype based on a 30-min observation. Agreement between the BDQ classification and classification based on the clinical observation was good, at 73%. Further analyses revealed that subtype assignment by the clinician was the most powerful predictor of BDQ assignment, indicating good external validity for the BDQ.

The authors also examined the consistency of parents' ratings across the 13 groups of descriptions, to assess the degree to which each subtype was rated in the same manner across behavioral domains. These analyses revealed that for all three subgroups, parents ranked the descriptions in a consistent manner. Correlations between the summary scores were computed to assess the extent to which each subtype was distinct from the others. The correlation between the aloof and passive groups was $-.02$, between the passive and active but odd groups it was $-.17$, and between the aloof and active but odd groups it was $-.70$. The high negative correlation between the aloof and active but odd groups was interpreted as evidence that these subtypes do in fact fall at two ends of a continuum.

In terms of behavioral correlates of the Wing subtypes, Castelloe and Dawson (1993) found that subtype classification was significantly related to mental age and score on the Childhood Autism Rating Scale (CARS), a measure of ASD symptoms (Schopler et al. 1986). The aloof group had the lowest mean mental age, the passive group occupied the intermediate position, and the active

but odd group had the highest mean mental age. CARS scores indicated a similar trend: the aloof group had the most severe ASD symptomatology, the active but odd group had the least severe ASD symptoms, and the passive group occupied the intermediate position. A trend in the same direction was seen for IQ, but it did not reach significance.

Overall, the data support the validity of the BDQ for classifying children with ASD into subgroups based on Wing's classification system.

Clinical Uses

The BDQ has been recommended as a useful addition to the assessment and treatment planning process (Powers 2005). Categorization of individuals with ASD according to social impairments allows for prediction of corresponding behavioral and cognitive differences (Castelloe and Dawson 1993). It has been suggested that the utility of such subtyping within ASD has the greatest clinical implications for the planning of treatment services (Wing and Attwood 1987).

Behavioral Health Rehabilitation (BHR) Services

Paul K. Cavanagh
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA

Definition

Behavioral Health Rehabilitation Services (BHRS) is a term used for a specific application of a Medicaid-funded interdisciplinary approach for a child or adolescent diagnosed with a serious emotional or behavioral disorder. The type of approach is sometimes referred to as a “wrap-around approach.”

Several states, and primarily Pennsylvania, support the provision of Behavioral Health

Rehabilitation Services when a licensed psychologist has deemed the service medically necessary as part of a Medicaid-funded Early and Periodic Screening, Diagnosis and Treatment (EPSDT) service. “The Early and Periodic Screening, Diagnostic, and Treatment (EPSDT) service is Medicaid’s comprehensive and preventive child health program for individuals under the age of 21. EPSDT was defined by law as part of the Omnibus Budget Reconciliation Act of 1989 (OBRA ‘89) legislation and includes periodic screening, vision, dental, and hearing services” (Centers for Medicare & Medicaid Services n.d.). The Medicaid EPSDT regulations provide for the provision of other necessary health care, when it will “correct or ameliorate defects, and physical and mental illnesses and conditions discovered by the screening services” (Centers for Medicare & Medicaid Services n.d.).

Historical Background

The United States Congress’s Omnibus Reconciliation Act of 1989 created a Medicaid service called the Early and Periodic Screening, Diagnosis, and Treatment (EPSDT) services. During the 1990s, several states, most notably the state of Pennsylvania’s Department of Public Welfare, supported the provision of Behavioral Health Rehabilitation Services when identified as medically necessary by a licensed psychologist or psychiatrist as part of an EPSDT evaluation. While, in theory, Behavioral Health Rehabilitation Services can be provided in any state as part of their Medicaid EPSDT services, Pennsylvania has been the most consistent at regularly providing this service.

Behavioral Health Rehabilitation (BHR) Services is essentially a form of wraparound services that is supported through Medicaid funding. The use of Behavioral Health Rehabilitation Services develops during the 1990s concurrent with the national development of wraparound services for youth with complicated mental health and behavioral needs in several discreet places throughout

the country. See the historical section of the Encyclopedia listing for wraparound services for more information on the development of the wrap-around philosophy.

Rationale or Underlying Theory

The key provision in Medicaid-funded Behavioral Health Rehabilitation Services is that a licensed psychologist or psychiatrist has determined that a child or adolescent has a medical need for the services in order to ensure the correction or amelioration of defects and physical and mental illnesses and conditions.

Behavioral Health Rehabilitation Services are individualized and interdisciplinary services for a child or adolescent with a significant behavioral health disability provided in the natural settings of their family or local community. An essential feature of BHR services is that they are designed and delivered at the sites where the problematic behaviors occur. Based on a philosophy consistent with wraparound services, the goal of BHR services is not to try to understand problematic behaviors in the abstract, but rather to provide direct intervention in the natural context with the professionals designing the interventions able to learn and respond directly from the child’s behavioral responses to the interventions.

Goals and Objectives

Behavioral Health Rehabilitation (BHR) Services are services based on a wraparound philosophy designed to provide comprehensive treatment to children and adolescents with a serious emotional or behavioral disorder who cannot make progress with the usual array of discreet services. An essential feature of BHR services is the coordination, or wraparound, of services in the child or adolescent’s natural environments of home, school, and the local community.

A primary goal of BHR services is to develop a natural community support network, and self-regulating behaviors on the part of the child or

adolescent, that can be maintained with the ordinary array of services. Thus, a key outcome for BHR services is to eliminate the need for BHR services.

BHR clinicians and other clinicians in the child or adolescent's natural environment, as well as with other concerned community members, work with the family of the child receiving services. Other concerned community members may include school administrators and teachers, members of a family's religious congregation, and civic officials, as well as staff at community, health, or recreation centers. BHR clinicians aid in developing and guiding a natural community support network. As a team, they develop individualized goals to promote appropriate behavior, activities, and academic and social skills in the child or adolescent's natural home, school, and community environments.

Treatment Participants

Treatment participants for Behavioral Health Rehabilitation (BHR) Services are children or adolescents who have been diagnosed with a severe emotional or behavioral disorder by a psychiatrist or psychologist after a face-to-face clinical evaluation. The prescribing clinician must identify that the BHR services are necessary in order to ameliorate or correct the identified severe emotional or behavioral disorder.

Treatment Procedures

Behavioral Health Rehabilitation (BHR) Services are not based on a single therapeutic model addressing the therapeutic needs of the children or adolescents with severe emotional or behavioral disorders identified as requiring the BHR services.

BHR services are based upon a wraparound philosophy of an individualized treatment plan utilizing all community resources based in and delivered at the place (or places) where the problematic behaviors occur.

While BHR services are not exactly the same as wraparound services – the implementation of BHR services is consistent with the wraparound philosophy. The National Wraparound Initiative has developed a set of ten Principles of Wraparound. These ten principles are as follows:

1. Family voice and choice: An emphasis on the primary importance of goals and perspective of the individual receiving services and their family and advocates in the development of the wraparound process. This principle stresses the importance of intentional activities to illicit and include the perspective of the individual receiving services and their family and advocates.
2. Team based: This principle stresses the importance of collaborative effort of family members, professionals, and other stakeholders committed to the family's well-being over an extended period of time. The choice of team members should be largely driven by the person receiving services and their family and advocates.
3. Natural supports: To the greatest extent possible, a wraparound plan of service should utilize the natural support systems of family members, friends, neighbors, church, and community members. The plan should also include the regular support structures that exist in the community via school systems, church congregations, community centers, local government, etc.
4. Collaboration: The decision-making process in developing a wraparound plan of service should be based on a consensus approach that includes input from all team members.
5. Community based: Wraparound services should adhere to a principle of provision in the least-restrictive setting possible.
6. Culturally competent: Team designation, service planning, and service delivery should demonstrate "respect for the values, preferences, beliefs, culture and identity of the child/youth and family, and their community" (Bruns et al. 2008, p. 7).
7. Individualized: Wraparound services need to be uniquely developed for the individual in

need and their family. The planning for services should draw upon the best empirical evidence of effective treatment and upon community and professional experience. However, the services should not be assembled from a static list of available services.

8. Strengths based: A key in the development of a wraparound plan of service is to identify, “build on, and enhance the capabilities, knowledge, skills, and assets of the child and family, their community, and other team members” (p. 8).
9. Unconditional: The origins of the wrap-around process grew out of a need to provide quality services to individuals with severe and complex behaviors. It is understood at the outset that this will be a difficult and challenging process. Inherent in the development of a wraparound plan of service is a commitment to see the process through despite setbacks and unanticipated behavior, events, or outcomes. There needs to be an unwavering commitment on the part of the team to continually adapt the plan of service until progress is made and there is consensus that a wraparound process is no longer needed.
10. Outcome based: Wraparound plans of service identify measurable outcomes and indicators of progress and success. The team measures and evaluates these measures on an ongoing basis and modifies plans accordingly (Bruns et al. 2008).

Efficacy Information

As of the summer of 2011, there is little or no published research specifically addressing the efficacy of the Behavioral Health Rehabilitation approach to service delivery.

The Institute for Behavior Change reports on their website information about research conducted by Dr. Natasha K. Brown and Erica Richman of the University of North Carolina at Chapel Hill. As reported on their website, the researchers “studied 301 treatment records of children age 3 to 17 between 2002 and 2007.

They found that Behavioral Health Rehabilitation Services (BHRS) as implemented by the staff of the Institute for Behavior Change had a statistically significant association with reductions in physical aggression, noncompliance with adult prompts, socialization deficits and communication deficits. An association was also found with improvements in the environmental safety of the children” (Institute for Behavioral Change n.d.-b, p. 1).

Behavioral Health Rehabilitation (BHR) Services are not the exact equivalent of wraparound services; nevertheless, their implementation is consistent with the basic philosophy of a wrap-around approach to services. The National Wrap-around Initiative has published a summary of nine controlled studies of wraparound services that had been reported in peer-reviewed journals as of 2010. Their conclusion of this very limited universe of research is that “though many of these studies have significant methodological weaknesses, the ‘weight of evidence’ of these studies indicates superior outcomes for youth who receive wraparound compared to similar youth who receive some alternative service” (p. 5).

Qualifications of Treatment Providers

As identified by Medicaid regulations and implemented by various states, the primary treatment providers for Behavioral Rehabilitation Services fall into three categories:

- *Behavioral Specialist Consultants (BSC)*: Behavioral specialist consultants are clinicians with a Master’s or PhD level of education who work with children, family members, and other members of the treatment team to develop the individualized BHR treatment plan. These clinicians take overall responsibility for overseeing the development and implementation of the treatment plan. In addition to developing and overseeing the treatment plan, they will work as advisors and mentors to all individuals providing services under the plan, including family and community members.

- *Mobile Therapist*: A mobile therapist is a Master's or PhD educated therapist who provides child-centered, family focused, individual, and family-level psychotherapy.
- *Therapeutic Staff Support*: A therapeutic staff support (TSS) worker is an individual with a Bachelors' degree or higher level of education, who provide one-on-one services addressing treatment plan goals. TSS workers are supervised by Behavioral Specialist Consultants and/or Mobile Therapists.

Behavioral Momentum

Shaunessy Egan

Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Behavioral momentum is derived from classical physics. In behavioral momentum, rate of responding is analogous to velocity and largely determined by the schedule of reinforcement, and the characteristic rate or magnitude of the obtained reinforcement in the situation determines the behavioral analogue of mass. The behavior momentum metaphor suggests that the more reinforcement in a condition correlates with greater resistance to change within that condition.

Behavioral momentum describes the relation between resistance to change (persistence of behavior) and the rate of reinforcement obtained in a given situation. Behavioral momentum refers to the tendency for behavior to persist after a change in environmental circumstances. The greater the rate of the reinforcement is the greater level of the behavioral momentum should be.

Behavioral momentum is frequently used as an intervention for noncompliance. Such intervention involves issuing a sequence of instructions with which the learner is most likely to comply (i.e., high-probability instructions) immediately prior to issuing a low-probability instruction.

Behavioral Objective

Marina Azimova

ABA Services of CT, West Hartford, CT, USA

Definition

A behavioral objective is a written statement that defines specific action (or pattern of actions) and set of measurements of a target behavior to be expected after an intervention. It contains the following necessary components: a description of the expected behavior itself, environmental circumstance(s) in which the behavior is to occur, and the standard criteria of acceptable behavior performance.

A behavioral objective is often expressed in the following format: *Given a set of conditions or circumstances, an individual will demonstrate the target behavior at performance level determined by rate, frequency, etc. in specified settings or with specific individuals.*

“Instruction, modelling, rehearsal, and feedback,”
BST

Definition

Behavioural Skills Training (BST) is an evidence-based, multicomponent training method that applies modelling, instruction, rehearsal, and feedback to teach individuals a wide variety of behaviors or skills.

Historical Background

Although there is strong evidence that the use of BST emerged in the late 1960s and early 1970s, it is unclear where the combined use of modelling, instruction, rehearsal, and feedback specifically originated. The main difficulty in finding the origin of BST stems from variations in the use of the BST term and its components in early research. For example, O'Connor (1972) taught 33 socially withdrawn children to engage in more social interactions through the use of video modelling and social reinforcement. In another study, Braukmann (1974) used instructions, modelling, practice, and feedback to teach adolescents interviewing skills. Despite these inconsistencies, the use of BST involving “modelling, instruction, rehearsal, and feedback” was first described within the context of applied behavior analysis (ABA) by Miltenberger (1997) in his conceptualization of the teaching strategy in *Behavior Modification: Principles and Procedures*. In his book, Miltenberger outlined BST as incorporating the following strategies:

1. **Modelling:** The target skill is first demonstrated to the student, which can be done in a variety of ways (e.g., “live” with other people, by video, through cartoons, etc.). For example, when teaching a child to brush his/her teeth, a parent could model grabbing the toothbrush, putting the toothpaste on, brushing his/her teeth, rinsing his/her mouth, and cleaning the toothbrush prior to the child’s brushing attempt. The model is presented first as an example of the behavior(s) that the child is to learn, so that the child can imitate the behaviors displayed. It is important to note that learners must be able to imitate others for this component of BST to be effective.
2. **Instruction:** The child is instructed to complete the behavior modeled in the task, by providing specific instructions regarding the steps needed to complete the behavior, the circumstances in which the behavior should be emitted, and what reinforcers will be provided contingent on engagement in the target behavior. For example, a parent of a child could state, “when it’s bedtime, you must brush the top, bottom, inside, and outside of your teeth. If you do so, you will have clean healthy teeth.” The instruction should incorporate language that will be easily understood by the child, and the instruction should be used in combination with the modelling to ensure acquisition of the behavior(s).
3. **Rehearsal:** The child performs the behavior(s) that were instructed and/or modeled. For instance, the parent who first modeled and instructed the child to brush their teeth would then next observe the child complete a rehearsal of the behavior(s). The purposes of the rehearsal are (a) so the parent can confirm the acquisition of the behavior(s), (b) whether the behavior(s) are completed incorrectly, and (c) contrive an opportunity to correct mistakes and reinforce correct responding.
4. **Feedback:** Immediately after the rehearsal occurs, the student is typically provided with feedback. Feedback always includes praise, and/or other reinforcers, whether the rehearsal was correct or not. In other words, if the student did not rehearse the skill correctly, praise

for attempting the rehearsal is typically provided. If the child in the example forgot to clean his toothbrush before putting it away, the parent could say, “Good job brushing your teeth with the toothpaste! Also, don’t forget to clean the toothbrush after your done. If you don’t it could grow bacteria and make you sick.” After praise has been provided, the parent uses descriptive language to identify correct and incorrect behaviors, avoiding the use of terms such as “bad” or “wrong.” Instead, feedback emphasizes the reason why a behavior was correct/incorrect, how it can be changed, and the reasoning for the form of the behavior.

The first empirical evidence of BST as a training tool for helping people with autism spectrum disorders (ASD) and their caregivers/staff was published in 2004 in a study that used BST to teach Discrete Trial Teaching (DTT) to three teachers of a student with ASD (i.e., Sarokoff & Sturmey, 2004). Since then, BST has become an increasingly popular method for training people with ASD, ASD caregivers, and ASD staff in the field of ABA. Considering that people with ASD often experience difficulties acquiring skills and communicating with others, which may ultimately result in a greater risk of engaging in property destruction, aggression, and self-injurious behaviors without proper, evidence-based treatment (McClintock et al. 2003; Lang et al., 2019; Gormley, Healy, Doherty, O’Regan, & Grey, 2019), the application of training methods, such as BST, is paramount for creating consistent teaching opportunities for people with ASD and to sustain quality of care for caregivers and direct care staff.

Current Knowledge

As BST is an evidence-based intervention, current applications of the method have been implemented to address a variety of behavioral and skill acquisition targets. Studies have demonstrated the utility of BST to teach academic, vocational, and leisure skills to individuals with ASD.

For example, Singh et al. (2017) used BST to effectively increase performance in four different comprehension-fostering areas (i.e., prediction, questioning, summarizing, and clarifying) for a child with ASD. The BST model was implemented for each skill area using explicit instruction, modelling, rehearsal, and feedback using praise or error correction. The results of the study by Singh et al. showed that BST was effective for teaching the fostering skills and improving overall reading comprehension scores (i.e., performance increased from an average of 40% to an average of 71% during intervention and 80% during follow-up). In addition to increasing academic skills, BST has been shown to be effective at teaching vocational skills to individuals with ASD. Morgan and Wine (2018) used a multiple baseline design to evaluate the effects of BST to teach work skills in a restaurant to an 18-year-old with ASD. Instructions regarding each step of a work task were read to the individual followed by modelling of the target skills. The individual was then given the opportunity to rehearse each step of the task and was provided with oral feedback for correct and incorrect steps. Feedback was delivered immediately following each step with specific praise for correct performance of the step or corrective feedback for steps performed incorrectly. Results of the study showed that the individual was able to increase performance for all four work skills (i.e., when rolling silverware, performance increased from 0% to 100% and 100% during maintenance and generalization probes in a novel environment). BST has also been used to teach leisure skills to people with ASD. For example, Thomas et al. (2016) taught five skateboarding skills to a child with ASD through the use of instructions, modelling the target skill, rehearsal, and feedback. In addition to the instructional component, the researcher reviewed the performance of the skill with the child by showing him his performance, describing the data sheet, and giving positive feedback for performing steps correctly and corrective feedback for steps that were performed incorrectly. Following the instructions component, the researcher continued implementing the remaining components of BST (modelling, rehearsal, and feedback) for all five

skills. The participant was able to acquire four out of five skills within two to nine training sessions. Post training, generalization, and novel skateboarding skills were also assessed, demonstrated, and maintained in a novel setting.

BST has also been demonstrated to be effective for teaching caregivers and staff to implement behavior analytic strategies with learners with ASD. This type of application of BST has allowed researchers to examine the effectiveness of both BST to teach a skill as well as the acquisition of the skill by the learner. Researchers have implemented BST with a variety of ASD direct care staff, including but not limited to special education teachers, dentists, and adult behavior technicians with an ASD. For example, Kirkpatrick, Akers, and Rivera (2019) conducted a systematic review of BST literature and found numerous studies that supported BST as a method for training special education teachers to use DTT and preference assessments in the classroom. Graudins et al. (2012) used modelling, instruction, rehearsal, and feedback to train oral care providers to apply basic and effective ABA strategies such as reinforcement or visual supports during routine dental care visits. After BST was implemented, three oral care providers accurately performed the ABA-based techniques while conducting oral exams and dental cleaning with children with ASD. Lerman et al. (2013) used BST to teach four adults with autism to perform discrete trial training (DTT) to a child with ASD. Following the BST-based training, three of four adult behavior technicians with ASD demonstrated an increase in correct responding for implementing DTT with children with ASD.

Traditionally, applications of BST are comprised of the four key components as described by Miltenberger (1997) including modelling, instruction, rehearsal, and feedback. However, research has demonstrated that some variations of this model can be implemented to effectively teach skills. Instructions can be given orally and/or written; modelling can be performed by the experimenter or via video modelling; rehearsal can be performed by the participant or by role-playing with the experimenter; feedback can be provided immediately during rehearsals or after completion

of the entire response; and training can occur in a simulated environment or in situ (i.e., in the environment the behavior is ultimately intended to occur). Unlike traditional BST that evaluates mastery of a target skill in simulated environments, training in situ allows for evaluation of the skills in the environment within which the behavior is most likely occur. Subsequently, in situ training can increase the likelihood that a skill will occur in additional novel, non-training situations and settings. In situ training has been utilized and demonstrated primarily in BST research aimed at teaching safety skills to children with ASD; but it has also been demonstrated to promote learning of other skills. For instance, Gunby and Rapp (2014) taught abduction-prevention skills to three children with ASD using BST and in situ feedback. Specifically, the experimenters taught the children how to respond to different abduction lures. In situ feedback was provided immediately following incorrect responses. For all three participants, abduction prevention skills taught using BST improved and maintained during training and follow-up when novel abduction lures were presented.

Within the BST model, the evaluation of how skills are measured has varied across researchers. Some researchers have measured performance by the percentage of correct opportunities, while others have used rating scales. For example, Singh et al. (2017) and Lerman et al. (2013) evaluated performance by calculating the percentage of correct responses. Alternatively, Gunby and Rapp (2014) and Houvouras and Harvey (2014) created rating scales and designated a score value for a specific behavior or set of behaviors (i.e., Likert scale). Specifically, Houvouras and Harvey evaluated BST to teach three boys with ASD fire safety skills (i.e., how to respond in the presence of a lighter). To assess performance, the researchers created a 4-point Likert scale in which each value specified the quality in which the step or steps were performed by the participants. The results showed that the participants were able to increase their scores (i.e., from a range of 0–1 on the Likert scale to a range of 2–3; with scores of 3 during maintenance probes) following BST using the four key components of BST.

Variations of BST demonstrate how the training method can be individualized to best teach a target skill while also maintaining the components that make up the BST training method. However, because BST is a multicomponent package, one or more of its components may, at times, be solely responsible for increasing and improving target skills. Through the use of component analyses (i.e., analyses that systematically evaluate the effects of individual components that comprise intervention packages to determine the component or components responsible for positive effects), researchers and clinicians can identify the BST components necessary to bring about skill acquisition based on learner needs and the behavior of interest. At the time of this publication, research has shown inconsistent results determining which component or combination of component(s) are necessary. For example, some studies have identified feedback and modelling as necessary components (e.g., Ward & Sturmey, 2012), whereas others have indicated that instructions and modelling are necessary to the effectiveness of BST (e.g., Kornack et al. 2013; Driftke et al. 2017). Findings across numerous studies, however, have been consistent in showing that the use of only one or two components of BST seldom increases skill acquisition to mastery levels. Thus, the use of BST as a full package has been shown to be the most effective way of teaching skills to mastery levels and maintaining performance across time.

Future Directions

The use of BST with people with ASD, their caregivers, and direct care staff is well documented and substantially supported by research. BST can be used in a variety of ways to increase and shape the form of behaviors in a reliable manner. To illustrate, we provided examples of how BST can be used to teach learners with ASD to communicate, engage in social interactions, increase their reading comprehension, and even teach someone with ASD to skateboard. It is likely that BST is an effective and increasingly popular training method because of its versatility.

Specifically, it can be used to teach virtually any behavior, or chain of behaviors, as it can be adapted and used with other resources (e.g., videos, manuals) to provide individualized training for learners. Despite the robust support in the literature for BST methods, continued examination of BST and its components with various populations, target skills, and with more variation has been suggested by researchers.

A consistent topic brought up by current BST researchers is the need for closing the “research-to-practice gap” (i.e., the inconsistent application of relevant and current research in locations/environments where they are most needed). For example, Gormley et al. (2019) noted that although most training of other professionals involved some level of individualization, BST has not been employed despite the evidence supporting BST as a reliable method that can be individualized to train specific behaviors or set of behaviors. Kirkpatrick, Akers, and Rivera (2019), in a systematic review of the literature, noted that BST tends to be used with special education teachers, but not with general education teachers. Further, a review by van der Meer et al. (2017) that examined 22 studies in which training was provided to direct care staff on the implementation of communication interventions found that although all the reviewed interventions indicated positive outcomes for the staff and the individuals with intellectual disabilities, only one study utilized all BST components in its teaching package. Rather, the review indicated that direct care staff were trained with various methods such as presentations, didactic instructions, group discussions, role-play, and structured practice with feedback. In addition to the research-to-practice gap, there is a notable gap between the use of BST between clinicians and non-clinic service providers. For example, Gaudins et al. (2012) indicated that BST was useful in teaching oral care providers how to use ABA-based techniques. Although the results of Gaudins et al. demonstrated effectiveness, there is a paucity of research related to the use of BST in this capacity. The same type of approach used by Gaudins et al. could be done with other community-based individuals such as firemen, policemen, hairdressers, and other

professionals to facilitate interactions between individuals with ASD and professionals in service industries. Given the consistent identification by literature reviews regarding the research-to-practice gap, future studies should try to expand the knowledge base regarding BST with individuals outside the field of ABA.

In addition to closing the research-to-practice gap, there is a need to identify the necessary training components within BST and the effectiveness of BST relative to other teaching methodologies. Some studies have indicated that modelling and feedback are the most important components of BST (e.g., Ward & Sturmey, 2012), while others have indicated that instructions and modelling are more important (e.g., Driftke et al. 2017); other studies have suggested that necessary components are idiosyncratic to each learner (e.g., Kornack et al. 2013). It is important to note that previous BST component analysis-based studies have targeted different skills and behaviors. Thus, caution is needed in terms of inferring external validity with regard to these studies. In other words, behaviors or skills that were taught in respective component analysis-based studies varied across studies, possibly contributing to the varying results. Accordingly, it is important that researchers continue to replicate and extend component analysis-based research regarding BST to continue to evaluate and document the circumstances in which some or all components are necessary to produce positive outcomes. Similarly, more comparative analysis-based research is needed to evaluate the effectiveness of BST relative to other training strategies. Leaf et al. (2015) conducted a review of studies that compared BST to another prominent ABA-based teaching strategy, the Teaching Interaction Procedure (TIP). The authors concluded that even though both interventions were effective at teaching a behavior or skill, none of the studies reviewed provided quantitative measurements that compared one to the other. Future studies could focus on comparing the effectiveness of BST and TIP by measuring trials to criterion, overall training time, and/or other dimensions to determine the most efficient strategy. Leaf et al. also noted that multiple studies have used the

components of BST and mislabelled them as *TIP* and vice versa. It is likely that these misidentifications are due to lack of training with multiple teaching methodologies. Considering the acknowledged presence of a research-to-practice gap, future efforts of researchers should focus on educating professionals on various types of teaching strategies and their respective components.

Behaviorally Based Social Skill Groups

Justin B. Leaf, Joseph H. Cihon and Julia L. Ferguson
Autism Partnership Foundation,
Seal Beach, CA, USA

Definition

Today one of the most commonly implemented and endorsed interventions are procedures based upon the principles of applied behavior analysis (ABA; Smith 2012). Although, behaviorally based interventions are commonly implemented in a one-to-one instructional format, research has shown that these interventions can be efficacious within a group instructional format (e.g., Dotson et al. 2010). One form of behaviorally based intervention is the implementation of behaviorally based social skills groups. Reichow and Volkmar (2010) categorize social skills groups as “groups contained two or more like-aged individuals (with and/or without disabilities) meeting in a group instructional format...” (p. 152). For an intervention to be considered a behaviorally based social skills group, the interventionists must implement only behavior

analytic procedures (e.g., behavioral skills training, discrete trial teaching, incidental teaching, or the teaching interaction procedure) and must only implement procedures that are evidence based, empirically based, and not pseudoscientific or antiscientific.

Historical Background

There has been a long history of the implementation of behaviorally based social skills groups for individuals diagnosed with autism spectrum disorder (ASD). Some of the early work took place at the UCLA Young Autism Project, where techniques such as discrete trial teaching occurred in one-to-one instructional formats and group instructional formats (Lovaas 1987; Smith and Lovaas 1998). Since the early days of behaviorally based social skills groups implemented in a clinic-based setting, there have been numerous single-subject and group design studies that have shown the effectiveness of social skills groups (see Williams White et al. (2007) and Reichow and Volkmar (2010) for a more complete review). One of the major milestones in the terms of the empirical research was researchers evaluating social skills groups with randomized group designs, most notably with the evaluation of the UCLA PEERS program (Laugeson et al. 2009). The authors and developers of this model demonstrated that a manualized approach to a social skills group, with parental support, can be effective in improving the lives of adolescents diagnosed with ASD. More recently, Leaf et al. (2017) used a randomized control trial to demonstrate the effectiveness of a behaviorally based social skills group for young children diagnosed with ASD. The results indicated that behaviorally based social skills groups can yield significant improvements to the social behavior of young individuals diagnosed with ASD. The results also demonstrated that a model in which interventionists are permitted to make in-the-moment decisions without a strict protocol (i.e., a progressive model of ABA) can be effective within a behaviorally based social skills group.

Rationale or Underlying Theory

Behaviorally based social skills groups are deeply rooted in the philosophy of behavior analysis. Within this philosophy, behavior is the result of the individual's interaction with his or her environment. More specifically, the probability of a response, or response class, occurring is increased when it is followed by a reinforcing event, and decreased when followed by a punishing event. In addition to the manipulation of reinforcing or punishing events, interventionists manipulate the potency of these events (e.g., establishing and abolishing operations), find effective ways to increase the likelihood of the student(s) responding correctly (e.g., prompting and prompt fading), and transfer learned behaviors with the interventionist, or within the context of the social skills group, to the individual's natural environment. Finally, interventionists make decisions based upon objective data as opposed to anecdotal or subjective evidence.

Goals and Objectives

The overall purpose of behaviorally based social skills groups is to improve specific social behaviors (e.g., joint attention, greetings, and sharing) as well as more global social behaviors (e.g., pragmatics, social learning, and social relatedness) for individuals diagnosed with ASD, with the ultimate goal of improving pro-social relationships and developing meaningful friendships for the individuals receiving intervention. Interventionists should target the improvement of a variety of social behaviors when implementing social skills groups. Some of the skills that can be taught are social communication, social interaction, social awareness, social learning, and social relatedness (Taubman et al. 2011). When interventionists teach social communication skills (e.g., changing the game when bored or providing compliments), the goal is to teach the student how to use and understand the social aspects of communication. When interventionists teach social interaction skills (e.g.,

joining into a game or sportsmanship), the goal is to teach the student skills that will help promote successful interactions with the student's peers. When interventionists teach social awareness skills (e.g., relationship identification or theory of mind), the goal is to teach the student how to pick up on social cues and discriminate between different social cues. When interventionists teach social learning skills (e.g., observational learning or vicarious learning), the goal is to teach the student how to learn from their environment without direct instruction. When interventionists teach social relatedness skills (e.g., tolerating peers or accepting peers), the goal is to teach the student how to have meaningful connections with his or her peers. All of these skills can be taught within the context of a behaviorally based social skills group and can improve the quality of life for individuals diagnosed with ASD. Additionally, within the context of behaviorally based social skills groups, the interventionists might also focus on teaching language, learning how to learn skills, self-help skills, and decreasing any aberrant or interfering behavior(s).

Treatment Participants

Although there is an underlying assumption that behaviorally based social skills groups are only effective for higher functioning and older individuals diagnosed with ASD, they can be successfully implemented with a wide age range of individuals across several demographics. Although behaviorally based social skills groups can be implemented with a heterogeneous group of participants, our research and clinical experience has shown that behaviorally based social skills groups are more effective for the participants and easier for interventionists if the groups are homogenous (Dotson et al. 2010; Leaf et al. 2017). Thus, interventionists should attempt to include participants in the group around the same chronological age (i.e., not developmental age), that display the same deficits in social behavior, have the same level of language, and display the same level of aberrant behavior. Ideally, students

should display minimal amounts of aberrant behavior prior to entering a social skills group, especially, if this behavior is harmful to the individual (i.e., self-injurious) or may be harmful to peers (i.e., aggression). Additionally, if a participant displays high rates of stereotypic behavior, that participant might not be the best fit for a social skills group as stereotypic behavior may interfere with the learning process (Cunningham and Schreibman 2008). Finally, if the interventionists have not identified and/or conditioned effective reinforcers, they should not start the participant in a behaviorally based social skills group, as the interventionists will not be able to effectively reinforce appropriate social behavior.

Treatment Procedures

What distinguishes behaviorally based social skills groups compared to other social skills groups implemented for individuals diagnosed with ASD is that the interventionists only implement procedures based upon the principles of ABA, using only evidenced-based and empirically supported procedures, with the goal to improve observable and measurable behavior. As such, interventionists do not utilize mentalistic interpretations to target social behavior, refrain from utilizing an eclectic approach, and refrain from implementing pseudoscientific procedures. Within a behaviorally based social skills group, the goal of the interventionists should be to minimize downtime of the learner and to maximize teaching opportunities. This can be accomplished by either following strict protocols (Laugeson et al. 2009) or using in-the-moment decision-making informed by clinical judgment (Leaf et al. 2017). Overall, behaviorally based social skills groups should be implemented at least once a week, but it is highly recommended to implement more frequently. It is also recommended that each behaviorally based social skills group run for at least 2 h in duration. A final overall component is that parent involvement should occur at some level, ranging from parents observing sessions (Leaf et al. 2017) to being

directly involved in the intervention (Laugeson et al. 2009).

Within the context of a behaviorally based social skills group, there are several different procedures that can be implemented, all of which have empirical support and have been implemented in one-to-one instructional formats. One procedure that can be implemented in a behaviorally based social skills group is group discrete trial teaching (e.g., Taubman et al. 2001). Within this procedure, the interventionist provides an instruction to a learner(s), allows time to respond, and provides either reinforcement for correct responding or corrective feedback for incorrect responding. The interventionists could provide discrete trials sequentially where one student responds at a time or chorally where all students respond together.

Another procedure that can be implemented in the context of a behaviorally based social skills group is video modeling (Wang and Koyama 2014). Within video modeling, the interventionists would show a video of either an adult, a peer, or the participants themselves engaging in a targeted social behavior. After the video has been watched by the learners, the learners have the opportunity to practice the targeted social behavior(s). Another approach that can be used within behaviorally based social skills groups is incidental teaching (Hart and Risley 1975). In incidental teaching, the interventionists arrange opportunities for the learner to engage in the behavior, follow the learners lead, and when they engage in the target social behavior, the interventionist can provide prompting, error correction, and/or reinforcement. Interventionists can also embed instructions into the context of games. When interventionists do this, they create opportunities in which the learners can respond to multiple simultaneous implicit instructions that occur within the context of the game/activity.

Interventionists can also implement a social discrimination program called the Cool versus Not Cool (CNC; e.g., Leaf et al. 2016) procedure. The CNC procedure consists of the teacher modeling a targeted social behavior correctly (i.e., “Cool”) and incorrectly (i.e., “Not Cool”).

After the demonstration, the learners have an opportunity to state, or label, if the model was “cool” or “not cool” and why the demonstration was “cool” or “not cool.” After the learner labels the social behavior, the learners have an opportunity to role-play the targeted behavior the cool way. A similar procedure that can be implemented in the context of behaviorally based social skills group is the teaching interaction procedure (TIP; Leaf et al. 2015). The TIP is a multicomponent teaching procedure which consists of the interventionist describing the targeted social behavior, providing cues and characteristics of when to engage in the desired social behavior, providing a meaningful rationale of why the learner should engage in the targeted social behavior, breaking the social behavior into smaller components (i.e., task analysis), modeling the targeted social behavior the cool and not cool way, providing the opportunity for the learners to role-play the behavior, and providing differential consequences throughout. Along with these procedures, interventionists could also implement script fading (e.g., Pollard et al. 2012), behavioral skills training (e.g., Miltenberger et al. 2009), and peer-mediated interventions (e.g., Odom et al. 1985) in the context of behaviorally based social skills groups.

Efficacy Information

Through the use of single-subject designs and group designs, researchers have shown that the implementation of behaviorally based social skill groups can be an effective way to improve social behavior for individuals diagnosed with ASD (e.g., Dotson et al. 2010; Leaf et al. 2017). Researchers have evaluated specific interventions (described previously) and have shown that these interventions can lead to learners with ASD learning and engaging in social behaviors such as joint attention, game play, and improved social language (see Williams White et al. (2007) and Reichow and Volkmar (2010) for a more complete review). Researchers have also evaluated the overall effects of behaviorally based social skills groups on improving the overall

social behavior of individuals diagnosed with ASD (e.g., Laugeson et al. 2009; Leaf et al. 2017). In these studies, the results have shown that individuals who receive intervention within behaviorally based social skill groups demonstrate an overall improvement in social behavior as compared to individuals who did not receive intervention within a behaviorally based social skill groups. Furthermore, the results of these group design studies have indicated that the individuals who did receive behaviorally based social skill groups maintained the improvements in social behavior overtime and that these social behaviors generalized to other settings (Leaf et al. 2017).

Outcome Measurement

When measuring improvements in social behavior, it is important to evaluate observable behaviors as opposed to what the learners say they should be doing, or evaluating mentalistic interpretations of behavior. Researchers should use a combination of measures to evaluate improvements in specific social behaviors (e.g., joint attention, sharing, social communication) and overall social improvement (e.g., overall quality of play, overall social interaction, and friendship development). When evaluating improvements on specific social behaviors, the researchers should conduct naturalistic and generalization probes. When implementing naturalistic and generalization probes, the researchers set up an opportunity for the learner(s) to display the targeted social behavior without providing any additional consequences (i.e., consequences other than those occurring naturally) or prompting. For example, if the targeted social behavior is losing graciously, the researcher would set up a game (e.g., the card game war) between a peer/adult and the learner(s) and see how the learner(s) respond when he or she loses the game. Naturalistic probes would be conducted within the context of the social skills group, while generalization probes would be conducted in the learner(s) natural environment (e.g., home, school, community).

Both naturalistic and generalization probes should be evaluated in conjunction with scoring on standardized assessments. There are numerous assessments which could be used when evaluating the overall social behavior of individuals diagnosed with ASD these include: the Vineland Adaptive Behavior Scales, the Social Skills Improvement System, Social Responsiveness Scale, The Walker-McConnell Scale of Social Competence and School Adjustment, the Friendship Qualities Scale, and the Aberrant Behavior Checklist. Within the research, there have been multiple evaluators who have scored these various assessments. The multiple evaluators have included parents, social skills group teachers, outside teachers, and blind evaluators (e.g., Leaf et al. 2017). Within clinical practice and research studies, it is encouraged that multiple people evaluate the participants across these various assessments. It is also encouraged that one of evaluators be blind to the study or clinical implementation of the behaviorally based social skill groups in order to minimize the chance for potential biases.

Qualifications of Treatment Providers

There are no specific credentials or certifications which are required for a professional to implement behaviorally based social skill groups for individuals diagnosed with ASD. What is required is that the professional is well trained in the principles of behavior analysis and is not just trained on how to simply follow a set of procedures or rules. It is not enough for a professional to know how to follow a protocol on the implementation of video modeling, but rather, the professional needs a thorough understanding of the principles behind video modeling. Professionals also need to be fluent in the implementation of a variety of procedures (e.g., video modeling, CNC, TIP) within the context of social skills groups. Additionally, the professional should be well trained in social curriculum and curriculum development to ensure the teaching of meaningful and functional social curriculum. Furthermore, professionals should be trained in

how to work collaboratively and supportively with parents. This training must be intensive (i.e., more than 40 h of general training in behavior analytic principles) and an individual should not be considered competent based on any time requirement (e.g., 40, 1000, or 1500 h) or solely on responses to questions or scenarios (e.g., performance on a multiple choice test). Rather, competency should be determined based on a performance-based assessment, in addition to any written assessments. Although, it is more important that a professional is qualified rather than certified, it may be a requirement by some third-party payers that a professional be certified or licensed. If this is the case, it is important that the professional understand that a certification or license does not necessarily mean that the professional is qualified to implement a behaviorally based social skill group.

Behaviorism

John Molteni

Institute for Autism and Behavioral Studies,
University of Saint Joseph, West Hartford, CT,
USA

Definition

Behaviorism is a philosophy of science where behavior is the unit of study and several suppositions about the science of behavior are made. Behaviorism focuses on the study of behavioral phenomenon that function under the same principles of conditioning. This includes behaviors that are both public and private. Finally, use of mentalistic terminology (e.g., I feel, I think, I believe) is not helpful in examining behavior and, in fact, ends the examination of a phenomenon.

There is some confusion when discussing behaviorism, particularly the radical behaviorist position of B. F. Skinner by critics wherein people assume that covert behaviors or behavior that occurs “under the skin” such as thoughts and feelings are not important to the study of behavior. The main impediment to using private events, those internal to the individual, is the difficulty in corroborating these events by another individual. Given the need for objective measurement of behavioral phenomenon, the inability to observe internal events makes inclusion of private events a challenge in discussing and defining behavioral principles.

The challenge for behaviorism is presenting behavior as the primary unit of analysis for psychology where the general public tends to support the idea that the “mind” or mental events are the focus and cause of a person’s behavior. Mentalistic concepts such as frustration, anxiety, depression, or anger are not helpful in our understanding of behavior and were deemed “explanatory fictions” by Skinner. Such concepts do not add to our understanding of behavioral phenomena; rather, they end the analysis. Behaviorists look to the behavioral manifestations of what is termed frustration, anxiety, depression, and anger and attempt

to explore the environmental stimuli that function to maintain and reinforce said manifestations.

Behaviorism maintains that behaviors that are overt (observable) and private (“within the skin”) can both be subjected to objective observations with the latter suffering from the challenges noted above with regard to corroboration of a second observer. Therefore, some behaviorists view thinking and feeling as behavior in the same way as overt behaviors such as running, typing, and speaking. While there is some discussion about the utility of attempting to analyze these covert behaviors (see discussion below), there is no argument that individuals engage in covert behavior.

Three type of behaviorism are generally discussed:

Methodological Behaviorism – The study of behavior should focus only on those behaviors that are observable and that no mental states should be considered in the analysis. This is most closely associated with John Watson.

Psychological Behaviorism – Associated with B. F. Skinner, psychological behaviorists focus on the functional relationship between environmental events (antecedents and consequences) and the behaviors produced by those environmental events.

Analytical Behaviorism – A behaviorist position that posits that mental states can be explained through consistent patterns of behavior. These patterns can lead to predictions of an individual’s behavior given a specific set of environmental stimuli.

Historical Background

Behaviorism has links to several philosophical schools including:

Associationism – Classical associationism dealt with the organization of ideas based on relationships between mental states and can be seen in writings as far back as Aristotle. David Hume presented a model of associationism that suggested that our understanding of reality was a product of three laws of

association. These included the Law of Resemblance, things that are similar are associated; the Law of Contiguity, things that occur close in time will be associated; and the Law of Cause and Effect, the most important aspect of associationism wherein the individual identifies causal influences on the environment. This is the basis of scientific inquiry.

Logical Positivism – A philosophical perspective that posits the only true knowledge is knowledge derived from scientific endeavors. Metaphysical explanations are to be abandoned as they cannot be demonstrated empirically.

Behaviorists

John Watson is considered the earliest psychologist to identify himself as a behaviorist. In his work *Psychology as the Behaviorist Views It*, he described the power of behavioral approaches and suggested that psychology should be the science of behavior and not the mind. Watson’s work was with reflexive behavior (see below) and therefore was responding to a limited amount of information on behavior and its relationship with the environment. His work led to significant criticism and a backlash from traditional psychologists who viewed his claims as boastful and whose methods generally consisted of introspection or turning inward for causes of behavior rather than to environmental influences.

Pavlov – Ivan Pavlov’s classic experiments on classical conditioning, (see below), demonstrated a conditioning paradigm that involved reflective behavior similar to Watson. In his classic experiments, Pavlov paired a neutral stimulus (NS), or a stimulus with which the organism does not have any learning history with, with an unconditioned stimulus (UCS), a stimulus that elicits an unconditioned response, a reflex response that occurs in the presence of the UCS. In Pavlov’s experiments, the neutral stimulus was a tone and the unconditioned stimulus was the presentation of food. In response to the presentation of the food, the organism, a dog, salivated. Through repeated pairings of a tone (NS) and the food (UCS), the tone began to elicit the response of salivation without the presence of the food. The tone had become a conditioned stimulus (CS) that elicited

the conditioned response (salivation). The diagram below outlines this process.

E. L. Thorndike – Thorndike’s experimental work led to his theory of Connectionism and the Law of Effect. He examined learning processes in experiments with animals. Animals, generally cats, were placed in a puzzle box that required the animal to perform an action to escape the box and receive a reward. Thorndike observed that the time animals took to perform an action (e.g., lever press) decreased after successful attempts to escape. Additionally, animals did not demonstrate the required action after observing other animals engaging in the behavior. This led to Thorndike’s formulation of a cause/effect description of learning. He tracked “learning curves” in the behavior of animals to demonstrate that learning was a gradual process of trial and error. Thorndike’s Law of Effect indicates that behavior that is followed by positive consequences is likely to be repeated in the future.

Hull – Clark Hull presented a theory of learning termed drive-reduction theory. Drive-reduction theory suggests that behaviors occur in response to internal drives of the organism. Drives are generally important for survival including hunger, thirst, and warmth. Stress on the organism leads to behaviors that reduce the drive and reduce stress. Drive reduction reinforces the organism and those behaviors will occur more frequently in the future. Hull’s theory presents a stimulus-response form of behaviorism where the stimulus (drive) elicits the behavior.

Skinner – Burrhus Frederick (B. F.) Skinner demonstrated operant conditioning procedures in laboratory settings. His work described the principles of behavior that serve as the foundation for the science of the experimental analysis of behavior and applied behavior analysis. Skinner’s radical behaviorism was borne out of his observations during experiments, not based on a theory of why organisms behave in a certain way. Skinner presents a response-stimulus understanding of behavior where the consequences that follow a behavior are crucial to the conditioning of behavior. Operant conditioning is so named as behaviors are emitted and operate on the environment. This is contrasted with behaviors that are elicited

by environmental events and are reflexive in nature. Skinner extended his work in the laboratory to extrapolations to the development of language, social engineering, and education in his later work. All of these extensions of his work were based in operant conditioning methodology.

Current Knowledge

Approaches

Methodological behaviorism is associated with John Watson following the publication of *Psychology as the Behaviorist Views It*. Within this paradigm, observable behavior is the only thing that should be studied and all things within the body should not be considered the realm of psychology.

Radical behaviorism was proposed by B. F. Skinner. The term radical behaviorism referred to the acknowledgement that a science of human behavior must account for covert behaviors (or behaviors within the skin) to be complete. The challenge for establishing the role of internal events into a functional analysis of behavior is that these are not accessible to anyone other than the individual being studied. This, therefore, does not allow for corroboration of these internal events as they are not observable.

Types of Conditioning

Respondent conditioning or classical conditioning is the process of conditioning reflexes to respond to environmental stimuli. This type of conditioning is also known as stimulus-response conditioning where the stimulus (S) precedes the response (R). This relationship is often represented as $S \rightarrow R$. In a traditional classical conditioning arrangement, a neutral stimulus (e.g., a flashing light) that has no previous history of being paired with the occurrence of the reflex (e.g., an eye blink) is presented along with a stimulus that elicits the reflex (e.g., a puff of air). The stimulus that elicits the reflex response is known as the unconditioned stimulus as it does not require a learning history to elicit the reflex or unconditioned response. After repeated pairings of the neutral stimulus with the unconditioned

stimulus, presentation of the neutral stimulus will come to elicit the unconditioned response without presenting the unconditioned stimulus. For this example, presenting the flashing light prior to the puff of air over multiple trials will eventually lead to the flashing light eliciting eye blinking without presenting the puff of air. This arrangement is represented as:

Neutral stimulus → *unconditioned stimulus*
→ *unconditioned response*.

With continued pairing of the neutral stimulus and the unconditioned stimulus, the neutral stimulus, now a conditioned stimulus, comes to control the occurrence of the unconditioned response, now called a conditioned response. This arrangement is represented as:

Conditioned stimulus → *conditioned response*.

When the conditioned stimulus is presented, the response follows as if the unconditioned stimulus had been presented. In this instance, behavior is elicited, that is, behavior is caused by the occurrence of an external stimulus. Continued presentation of the conditioned stimulus without the presentation of the unconditioned stimulus will gradually lead to reductions in the conditioned response. This process is termed extinction.

Operant conditioning occurs when a behavior comes under the control of consequences that follow it. The operant conditioning paradigm can be described in the three-term contingency:

Antecedent → *Behavior* → *Consequence*.

An antecedent is a stimulus event that precedes the occurrence of behavior where as a consequence is a stimulus event that follows the occurrence of the behavior. A behavior is anything an organism does and results in a change in the environment. During operant conditioning, an organism's behavior is subject to consequences that lead to increases (reinforcement) or decreases (punishment) in the future occurrence of that behavior. Along with these increases, antecedent stimulus events come to serve as discriminative

stimuli for the likelihood of reinforcement. That is, environmental events signal the availability of reinforcement if the organism engages in a particular repertoire of behavior. Skinner's work on shaping is instrumental to the development of learned repertoires of behavior. Shaping involves reinforcement of closer and closer approximations to the target behavior. For example, a rat in an operant chamber may be required to push a lever to access food (a reinforcer). As the rat moves about the cage and orients to the lever, a click is followed by the delivery of the reinforcer. As the rat begins to orient toward the lever more frequently, reinforcement is delivered and then withheld. This withholding is called extinction. Extinction leads to variability in responding where the rat may now touch the lever which would be followed by reinforcer delivery. This process continues until the rat reliably presses the lever. Shaping, extinction, and schedules of reinforcement serve as the basis for our understanding of the development of behavioral repertoires.

Molecular Versus Molar Behaviorism

The contrast of molar and molecular behaviorism represents the focus of attention in a functional analysis. Those who support a molecular view of behaviorism support looking at the moment to moment changes in behavior and analyze the direct antecedents to and consequences of those behaviors. This is a view that is in line with Skinner's analyses of behavior in his basic experimental work. A molar perspective looks at behavior over time and views behavior in the context of other, longer sequences (chains) of behavior. That is, when describing an event, one needs to observe the behavior to completion as opposed to a moment in time. Lever pressing is best understood as the duration of engaging in lever pressing and not in the instant where the lever is pressed. The molar view contrasts with the molecular view in terms of how responses are strengthened. The molecular view focuses on increases in response rates as an indicator of response strength. In contrast, the molar view focuses on increased allocation of responding to one or another behavior in a choice paradigm. That is, all behavior requires

choices between responses and the selection of one behavior over another is a function of reinforcement. There is ongoing discussion among behavior analysts as to which perspective best explains behavioral phenomena.

Applications

Experimental Analysis of Behavior – The experimental analysis of behavior has a primary focus on basic research, that is, research on human and nonhuman organisms whose purpose is to develop greater understanding of behavioral principles. This, in turn, enhances our understanding of conditions that reliably predict their occurrence. The experimental analysis of behavior is responsible for our understanding of reinforcement, schedules of reinforcement, and their impact on behavior, punishment, discriminative stimuli, and choice. Basic behavioral principles demonstrated in laboratory settings serve as the basis for procedures used in applied settings.

Applied Behavior Analysis – Applied behavior analysis focuses on the application of behavioral principles to socially important behavior (Baer et al. 1968). Applied behavior analysis limits its scope of focus to the improvement of socially important behavior. This is not a limitation of applied behavior analysis, but rather, the need to focus on those behaviors brought to our attention as needing improvement. Methods for assessing the environmental variables that control behavior are consistent between the experimental analysis of behavior and applied behavior analysis. Applied behavior analysis practices include application of reinforcement contingencies, stimulus control procedures, shaping, chaining, and task analysis and are applied to various populations and areas of practice. Applied behavior analysts have formed an accrediting body and established criteria for university coursework and supervision that leads to certification as a board-certified behavior analyst.

Future Directions

Behaviorists continue to evaluate and extend our understanding of the basic principles of behavior

and application of these principles to socially significant behaviors. Extensions to complex human behaviors continue to fields such as pharmacology, neuroscience, performance management, gun safety, interventions for addiction and gambling, and treatment for individuals with neurodevelopmental disorders including autism spectrum disorders.

Behaviorist Theory

Susan A. Mason

Services for Students with Autism Spectrum Disorders, Montgomery County Public Schools, Silver Spring, MD, USA

Definition

Behaviorism is widely used to refer to the philosophy of a science of behavior. More specifically, within the field of psychology, behaviorism

explains responses of humans and other animals only in relation to environmental stimuli and observable and measurable responses to those stimuli. There are various forms of behaviorism: structuralism; behaviorism that uses cognition as causal factors (e.g., cognitive behavior modification); social learning theory, in addition to methodological behaviorism; and radical behaviorism. In his text, *About Behaviorism*, B. F. Skinner (1974) wrote: "Behaviorism is not the science of human behavior, it is the philosophy of that science" (Cooper et al. 2007).

Historical Background

Prior to the introduction of behavioral science, the field of psychology consisted of the study of states of mind and mental processes. There are four historical building blocks of behaviorism: classical conditioning as presented by Pavlov, Thorndike's law of effect, Watson's experiments with human conditioning, and Skinner's conceptualization of operant conditioning.

The development of behaviorism is largely attributed to John B. Watson who wrote a seminal article in 1913 in which he argued that psychology should be viewed as a purely objective experimental branch of natural science. As such, the goal should be to study the prediction and control of behavior through direct observation of the relationship of environmental stimuli and resulting evoked responses. This relationship became known as the *stimulus-response (S-R)* paradigm, and Watson proposed that it could be used to predict and control human behavior in a way that would allow practitioners to improve performance in areas such as education, business, and law. Although Watson later made exaggerated claims about the ability to predict and control human behavior, he is recognized for providing a strong case that the study of behavior as a natural science is on par with physical and biological sciences (Cooper et al. 2007, p. 9). The premise that the study of behavior is a science was further expanded upon in a work by B.F. Skinner who was interested in providing scientific accounts of all behavior. Skinner's publication of *The*

Behavior of Organisms (1938, 1966) summarized his laboratory research and gave rise to two kinds of behavior, *respondent* and *operant*. Respondent behavior is behavior that is elicited by a stimulus; it is reflexive and essentially involuntary. Operant behavior is behavior that is influenced by stimulus changes (consequences) that follow the behavior. Skinner argued that the uniqueness of operant behavior warranted its own field of study (see also ► "[Behavior Analysis](#)"). Skinner conducted thousands of laboratory investigations that allowed him to systematically study functional relationships of antecedent stimuli, responses, and reinforcement of those responses in a controlled environment. Skinner's methodology resulted in the foundation of behavior analysis as we know it today.

Current Knowledge

Behaviorism has evolved into many areas of study. It is most widely represented in the disciplines of *experimental analysis of behavior* and *applied behavior analysis*. Within the field of applied behavior analysis, methods of behaviorism have been used to study and affect services in the areas of verbal behavior, public safety, organizational behavior, education, special education, habit reversal, behavioral medicine, cognitive behavior modification, and therapy including derived relational responding as it is related to relational frame theory and acceptance and commitment therapy, social learning theory, functional analysis and assessment of behaviors, and more. The foundation of behaviorism continues as a philosophy of a science of behavior.

Future Directions

As previously noted, behaviorism has been the underpinning for both experimental analysis of behavior and applied behavior analysis. As such, its methodology can be used to study many branches of behavior as long as the behaviors can be operationally defined and observable. As noted by Pear and Eldridge (1984, p. 459),

“Several alternatives to the operant respondent framework have been proposed, but there is no indication that any of these currently has comparable organizing power. Until such a paradigm is put forth, therefore, we see modification of the operant respondent framework, rather than its elimination, as the more fruitful approach.”

Description

The Bender Visual Gestalt II testing kit includes 16 stimulus cards that are separated into two tests. These stimulus cards include an improved version of the original nine designs and new cards that were constructed to be more fitting for the age range covered by the test. All of the stimulus cards have been mechanically drawn to increase the clarity of the design.

The administration of the Bender-Gestalt II is considered to be user-friendly and relatively easy. It occurs in two phases: the copy phase and the recall phase. During the copy phase, the examinee is presented with the age-appropriate stimulus cards one at a time and instructed to copy each design onto a blank, white sheet of paper using a No. 2 pencil. In the recall phase, the examinee is instructed to draw as many of the designs as they can from memory onto a new sheet of paper. While there are no time limits for any of the designs or phases, the examiner should begin timing immediately following the presentation of the first design, in order to keep track of the amount of time needed for the examinee to complete each separate design. The examiner should also pay attention to behavioral and physical characteristics of client. Such observation can help determine if poor reproductions of a design are the result of impaired motor or perception abilities.

To score the Bender-Gestalt II, a new Global Scoring System has been outlined. This scoring system evaluates the examinee reproduction of designs at the copy and recall phases and rates the quality on a five-point scale. A score of 0 is given to designs that have no resemblance to the design or are the product of random drawing or scribbling. A score of 4 is given to those designs that are nearly perfect in their resemblance to the design. This scoring system is considered to be fairly simple as specific examples of the Global Scoring System are provided in the manual. However, it requires rigid adherence to the scoring examples and much stricter than previous scoring methods.

Historical Background

The Bender Visual Motor Gestalt Test was first published in 1938 by the American Orthopsychiatric Association under the title of "A Visual Motor Gestalt Test and Its Clinical Use." It evolved from Max Wertheimer's early studies of a Gestalt theory of perception. Lauretta Bender adapted nine of Wertheimer's designs and put them on cards in order to understand the

gestalt experiences of psychiatric patients. Specifically, the test was designed as a screening measure to test the ability of the perceptual system to organize visual stimuli into configural wholes, as a screening measure for neuropsychological damage. It quickly grew in popularity because it was brief and fairly simple to score and administer. Since its original development, the test has undergone many revisions that have largely focused on changes in interpretation and scoring procedures.

A wide variety of scoring procedures have been developed over the years using the original Bender-Gestalt Test. Among the most notable are the Koppitz's Developmental Bender Scoring System, published in 1964 as *The Bender-Gestalt Test for Young Children*, and Max Hutt's Scoring System. Under Koppitz scoring system, 30 discrete errors are scored if present, with each design ranging from 2 to 4 possible errors. This scoring procedure was designed to measure neuropsychological impairment and the developmental maturation of children. Hutt's Scoring System, on the other hand, was designed to use the Bender-Gestalt Test as a projective personality assessment for adults. It scored tests based on the frequency and severity with which an examinee deviated from protocol. Koppitz's original scoring system was adapted after her death by Cecil Reynolds (2007).

Notable psychometric problems with the original version limit interpretation of data from studies utilizing that test. Several studies in the earliest history of autism research utilized the original version of the Bender, but in the context of psychometric problems with the test as well as the lack of standardized diagnostic criteria for autism, these studies are not considered relevant.

The test was included in Norcross et al. (2006) list of "Discredited Psychological Treatments and Tests" based on ratings by a large expert panel, either for use in screening neuropsychological impairment or personality function. This presumably referred to the original version of the test and its uses, rather than to the revised Bender-Gestalt II.

The second edition of the Bender Visual-Motor Gestalt Test was published in 2003. This new

edition is a product of many years of analysis with the first edition of the test, as well as modern research in the fields of psychological testing and test construction. This comprehensive revision added four easier items and three harder items in order to increase the measurement scale. In other words, it lowered the “floor” of the test and created a higher “ceiling” so as to better describe those individuals who score on the extremes of the spectrum.

Psychometric Data

The Bender-Gestalt II was normed from a stratified, random sampling of 4000 subjects that comparatively matched US census data from the year 2000. T-scores, percentile ranks, confidence intervals, and classification labels are available for subjects ages 4 to 85+ years.

The psychometric properties of the test are fairly strong. Interrater reliability is reported at a range of .83 to .84 for the copy phase and .94 to .97 for the recall phase. A validity of .91 was found using split-half procedures. Over a 2–3 week interval, test-retest reliability is between .80 and .88 for the copy phase and .80 to .86 for the recall phase.

Construct validity for the Bender-Gestalt II has been supported by moderate correlations to other measures. For example, it has moderate correlation of .65 with the Beery-Buktenica Developmental Test of Visual-Motor Integration and a correlation of .75 with the Perceptual Organization factor on the WISC-III.

Clinical Uses

The Bender Gestalt II is designed to assess the visual-motor integration abilities of children and adults from 4 to 85+ years of age. It is also designed to be used as a test of motor memory in children and adults ages 5 to 85+. It has been used to identify brain dysfunction in children and adults, and discern emotional problems in children. Generally, if the Bender-Gestalt II is being used to assess for brain damage, it should be

considered a screening device as it is limited to severe forms of brain damage.

Allen and Decker (2008) found significant differences to indicate impaired performance, after controlling for IQ, in a moderately sized sample of children (mean age = 11) diagnosed with attention-deficit/hyperactivity disorder compared to a healthy comparison group, suggesting possible utility as a measure of function in other disorders autism. Effect sizes were very small, however. One study (Volker et al. 2010) has used the Bender Gestalt II to analyze the visual-motor skills of individuals with autism spectrum disorders. In demographically matched subsamples of ASD and healthy children (mean age = 9.7; $n = 27$ for each group), and after statistical control for IQ, a high-functioning autism spectrum disorder group scored lower than the comparison group on the two tests most sensitive to motor function (the copy and supplemental motor scales).

There appears to be substantial justification for continued investigation of atypical motor function in autism. A recent review by Dowd et al. (2010) notes the potential utility of motor function as (a) a diagnostic marker of autism, (b) an endophenotype of autism, and (c) a marker of severity of impairment, including social-communicative impairment. The Bender-Gestalt II could be used in future studies to characterize basic motor deficits and possibly higher order problems with visuomotor planning and organization.

Bender, Lauretta

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Lauretta Bender MD

- B.A. (1922) University of Chicago
- M.A. (1923) University of Chicago
- M.D. (1926) State of University of Iowa

Major Appointments (Institution, Location, Dates)

Bender held positions at the Hospital of the University of Chicago, the Boston Psychopathic Hospital, the University of Amsterdam, the Johns Hopkins University Hospital, and Bellevue Hospital in New York, as well as at the University of Maryland.

Major Honors and Awards

In 1955, Dr. Bender was the recipient of the Adolf Meyer Memorial Award from the American Psychiatric Association for her work on severe psychiatric disturbance in children.

Landmark Clinical, Scientific, and Professional Contributions

Loretta Bender was an early pioneer in the study of learning disabilities and severe psychiatric disturbance in children. Highly active at the professional level both as a clinician and researcher, she was involved in development of various approaches to treatment and to theories of childhood psychopathology. The Bender-Gestalt test remains in use today. Her view of learning disabilities was based on a theory related to discrepancies in areas of maturation, and she emphasized the confluence of various problems in children with learning problems that reflected their common origins. She also worked in the area of language difficulty and conducted some of the early work on reading disability. Her work was conducted at a time when childhood schizophrenia/childhood psychosis was used to describe all severe neuropsychiatric disturbance, i.e., before the distinction of autism as a distinctive diagnostic category was made.

Short Biography

A native of Butte, Montana, Lauretta Bender coped with a significant learning difficulty but persevered to become the valedictorian of her high school class. She received her B.A. (1922) and M.A. (1923) from the University of Chicago. She received an M.D. from the State of University of Iowa (1926). Bender held positions at the Hospital of the University of Chicago, the Boston Psychopathic Hospital, the University of Amsterdam, the Johns Hopkins University Hospital, and Bellevue Hospital in New York as well as at the University of Maryland. Bender was active in many ways at the professional level. She was Director of Research of the new Children's Unit

at Creedmoor State Hospital in the 1950s and while there conducted much of her work with severely impaired children.

Her first husband, the psychiatrist Paul Schuler (1886–1940), tragically died after a few years of marriage. She married Henry B. Parkes, a professor at New York University, in 1954.

Bender-Gestalt II

► [Bender Visual-Motor Gestalt Test II](#)

Beneficiary

John W. Thomas
Independent Educational Consultant, Durham,
NC, USA
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

Basic Definition

A beneficiary is a person for whose benefit property is placed in trust. The beneficiary is

the third of three ingredients critical to the creation of a trust: (1) property, usually money, placed in a trust administered by (2) a trustee for the benefit of (3) a beneficiary (restatement). A trust cannot exist without a beneficiary (Bogert, 121). On occasion, American courts refer to the beneficiary by the French phrase *cestui que trust*. A trust may have multiple beneficiaries. The trust documents dictate when and how much of the trust property a beneficiary will receive.

Who May Be a Beneficiary

Any legal entity, including individuals or corporations, may be a beneficiary (Bogert, 125).

But, only the entities intended by the creator of the trust, or settlor, to benefit from the trust may be a beneficiary. The settlor may be a beneficiary, and even the trustee may be a beneficiary as long as he or she is not the sole trustee.

Many trusts have multiple beneficiaries who can be named individually or can be designated as a “class,” such as all of the children of a particular person.

Rights of a Beneficiary

A beneficiary’s interest in a trust varies according to the type of trust created (Dietz). In a “fixed trust” in which the benefits are spelled out precisely by the trust documents, the beneficiary has an ownership interest in the trust proceeds. If the trust is a “discretionary trust,” meaning that the trustee has discretion as to when and how much of the trust property to give to the beneficiary, a beneficiary’s interest is subject to the determination of the trustee.

A beneficiary may refuse the benefits of the trust by disclaiming her right to them. The disclaimer may be implied by conduct “inconsistent with a trust for his” (Bogert, 170) ASD-related issues.

Benhaven Residential Services

Cynthia Beesley and Linda Rumanoff Simonson
Benhaven, Inc., North Haven, CT, USA

Definition

Benhaven is an agency that provides educational, day program, and residential supports to adults and adolescents with autism and developmental disabilities in New Haven, Connecticut, and surrounding towns. The residential services division of the program, which is the topic of discussion in this entry, entails a variety of programs including in-home consultation, family respite, professional parent settings, and group homes. In each setting, the emphasis is on individualized programming and is driven by the principles of positive behavioral support (Koegel et al. 1996; Lavigna and Donnellan 1986; Smull and Harrison 1992; Structured Teaching 2010).

Historical Background

Benhaven's residential services developed in response to the overwhelming need for such services in the early 1970s. Amy Lettick, the director and founder of Benhaven School and the mother of an autistic son, Ben, recognized that need. She believed that in order for many children with autism and their families to function optimally, the continuity and consistency of 24-h programming and care was necessary. In addition, during

the late 1960s and early 1970s, quality educational programs were few and far between, so the development of a residential program allowed Benhaven to accept many students in need.

Benhaven School was established in 1967, followed in 1972 by the purchase and development of one home, the beginning of Benhaven's residential program. With many more applicants looking for both school and residential support, more homes were opened, and by 1991, a total of 7 homes served 34 residents. In 1990, Benhaven introduced its Shared Living Program. This program gives people the opportunity to live in a typical home with the skilled support of licensed families and individuals. In 1996, the Individual and Family Support Services Program was created to provide support to children and families in their own home.

Benhaven has had a long-standing supportive relationship with the Yale Child Study Center, particularly with Dr. Fred Volkmar and the late Dr. Donald Cohen. In the mid-1980s and early 1990s, under the direction of its (now retired) Executive Director, Larry Wood, Benhaven underwent a major shift in its understanding of state-of-the-art approaches to teaching and supporting people with autism. Benhaven's administrative, teaching, and managerial staff received extensive training in structured teaching practices, functional behavioral support, and team building, conducted by expert leaders in the field, such as Dr. Gary LaVigna and Dr. Anne Donnellan. This training changed how Benhaven provides services to its program participants and training to its staff. This rigorous approach to staying informed about best practices in the field of autism has continued at Benhaven throughout the years. Under the leadership of Benhaven's new Executive Director, Kathryn DuPree, plans for further residential development to meet the growing need for adult residential services are underway.

Rationale or Underlying Theory

The rationale for Benhaven's approach to residential services is that, based on experience,

individuals with autism have a unique set of learning characteristics that respond well to a visual and structured approach to teaching. Positive behavioral intervention is an established approach that begins with understanding the factors that drive behavior through a process of functional analysis of problem behavior (Fox et al. 2000; O'Neill et al. 1997). When functions of behavior can be identified, an individualized behavior support plan is designed and implemented. The majority of interventions that make up the plan are preventative and positive in nature. They are aimed at maximizing a comfortable physical and social environment for the individual, recognizing and preventing triggers to challenging behavior, and teaching alternative, appropriate means of communicating needs and wishes. The plan also includes carefully planned interventions for managing challenging behavior when it does occur. This approach requires having knowledgeable, educated, and well-trained leadership as well as direct support staff and also requires that supporters' professional development plans include goals to establish positive relationships with the residents in their care.

The most important aspect of the relationship between support provider and the person receiving support is respect. Respect is the cornerstone upon which all support services should be rendered. The roles and tasks assumed by the provider of support will not be as effective if this foundation of respect is missing. The support provider's respect should not have to be earned. It must be there unconditionally.

Part of the challenge of this work is learning how to provide choices, honor preferences, and respect the person's individuality while satisfying the professional responsibilities associated with helping the person stay safe and healthy, helping the person learn, helping the person gain new experiences, and helping the person avoid disappointment or embarrassment. Responding to this challenge is what makes the work more of an art than a science. Balancing the role of supporting what the person wants with the temptation to control because "teacher knows best" can be frustrating, and supporters may find themselves too far in one direction or the other. Approaching the

work from the foundation of respect allows continual assessment of that balance while struggling to carry out multiple and sometimes conflicting roles. Constantly striving to learn and do better is part of the job.

Goals and Objectives

The approaches described here are intended to address issues that exist for people with autism as a result of the inability to communicate or relate to the social world in a typical way (American Psychiatric Association 2000). Challenging behavior is a frequent problem in autism and can be highly interfering to a person's relationship with one's family, to relationships with peers and teachers, to learning, and to one's ability to develop functional life skills and experience a broad range of opportunities. Challenging behavior is most often the result of a person's inability to communicate needs, desires, discomfort, and refusal, and many of the other things a person typically resolves through the use of spoken or symbolic language. Many people with autism, due to the social delay inherent in the disability from infancy, have not learned the vital process of getting needs met through social interactions with others (Volkmar and Wiesner 2009). In the absence of language or another way to express one's needs, maladaptive behavior evolves as an often successful means to quickly and effectively make choices, refuse to participate, or obtain something desired.

Other characteristics of autism, for example, distractibility, or need for sameness, can interfere with learning and compound a cognitive delay. Heightened senses in many people with autism create other barriers to participation. For example, a sensitivity to noises may limit the physical and social environments in which a person may be comfortable, in this way narrowing a person's experiences and learning opportunities. Additionally, each person with autism has a unique set of characteristics and a distinctive learning style. Given all these factors, supporting and teaching people with autism in a residential setting requires a multilayered approach.

One objective in this process is the thoughtful establishment of an environment that makes sense for an individual, taking into consideration both the physical aspects of a setting, such as the amount and type of space that are important, and the social environment, involving the number of others living and working in the setting. Another extremely important factor is the establishment of a means of communication for each individual, including the teaching of the skills necessary to utilize that communication method. A behavior support plan is a vital component of a residential program, which guides instructors in the prevention and response to whatever challenging behaviors may exist, while teaching appropriate alternatives to behavior.

Skill development is another objective of the program. Functional skills are taught in the context of caring for one's home and oneself while living with cognitive, communication, and behavioral challenges. Skills to participate in the community, including recreational as well as functional and employment settings, are also essential. Other goals of the program include establishing and/or building a person's relationship with his or her family and friends and attending to a person's health and medication needs. In short, the responsibility is to teach skills and provide opportunities to empower and equip residents with a range of appropriate choices and productive control that will enhance their quality of life.

Treatment Participants

Those who are most likely to benefit from treatment at Benhaven's residential program are individuals whose primary diagnosis fits the DSM-V diagnostic criteria for autism spectrum disorder and others with cognitive delays and behavioral symptoms similar to those experienced in autism. This is the case because treatment is designed to address the specific learning characteristics of people with autism. However, the strategies described here could be beneficial to others experiencing learning or behavioral challenges, since the primary characteristics involve individualized and structured teaching. While Benhaven's residential program

currently serves adolescents and adults, the treatment procedures are suitable for people with developmental disabilities of any age. Many of the program participants have additional psychiatric diagnoses that are addressed through consultation with outside providers. Because the treatment emphasis is on autism and symptoms of other developmental delay, those with other primary psychiatric diagnoses without cognitive delay would not be well suited to treatment at Benhaven's residential program.

Treatment Procedures

All treatments begin with the process of conducting assessments, which is the first step to designing an individualized program for a person with autism.

Functional Behavioral Assessment and Behavior Support Plan Development

A functional behavioral assessment is a means of identifying the important factors that contribute to the existence of challenging behavior in a person with autism. This process involves interviewing the team of people supporting the individual to determine what factors probably cause and maintain the target behavior(s). This process identifies likely functions of that behavior and tests these hypotheses through observation of the individual in his or her life settings to determine whether the identified functions are supported. Once functions of behavior are established, a series of strategies are developed in the form of an individualized behavior support plan. This plan lays out components to address the target behavior(s) from different angles. Preventative strategies are designed to predict and prevent behavior from happening through management of antecedent settings and events. For example, it might direct instructors to give a person a "heads up" that a difficult transition is coming. Rather than interrupting the person relaxing with a magazine and announcing "It's time to do your laundry," a situation that is likely to cause a target behavior to occur, the instructor may be directed to provide the individual with a verbal and visual countdown. The instructor will

verbally alert the person about the change in activity at 1-min intervals and will use a visual timer to more concretely help the person recognize the passage of time.

The behavior support plan also contains teaching and coping strategies. Coping strategies are means for a person to handle the challenges of the environment or demands in the daily schedule. For example, rather than striking out in frustration when the environment is too noisy or overwhelming, a person may be taught to simply leave the area for a quieter environment within his home. Or, a person may be taught to utilize calming techniques, such as music or deep breathing, when he senses himself becoming overwhelmed. He may also be taught a means to communicate his need, for example, saying “it’s too loud” as a means to ask an instructor to help find a quieter place. Teaching strategies teach a person to engage in alternative actions to the target behavior. These alternatives are meant to be positive and equally efficient ways to get the same needs met. When negative behavior is the result of inability to communicate in a functionally appropriate manner, teaching strategies will involve teaching a person a means to communicate something he was not able to initiate on his own before, such as a need, a desire to change activities or environment, or to refuse something. Teaching strategies also involve teaching a person skills to accomplish things that may have only been accomplished before through behavior, for example, learning to ask for a break rather than hitting the instructor to indicate frustration with the activity. Teaching strategies can also be a means to help someone predict events and have a sense of order in life through the use of visual schedules and scripts. This will be described further below.

Finally, behavior support plans contain strategies for providing consequences to challenging behavior and for responding to challenging behavior if and when it does occur. The term “consequence” refers to the events that occur immediately following the occurrence of a behavior, whether positive or negative. The way instructors respond to the behavior has a major impact on whether the behavior is strengthened or weakened. The goal, of course, is to strengthen positive behaviors and

weaken negative ones, so the strategies are designed to do just that. The consequence for engaging in a positive behavior, such as utilizing communication to ask for help, is to provide the help and offer praise for the communication. Done consistently, this will strengthen the communication response. Done inconsistently, for example, by saying, “I’m glad you asked for help, but I think you can do that on your own,” will result in a weak learning and erratic use of the skill. Concurrently, the response to negative behavior must be clearly designated and consistently applied. If the function of screaming at the instructor is to end the activity, then responding to screaming by ending the activity will maintain that behavior. Rather, the plan might designate that breaks are initially built in after very short work periods, preempting the person from becoming frustrated and acting out. The resident is shown how to ask for a break, perhaps by sign, picture, or words, and then is guided to do that before any frustration sets in. He is immediately rewarded with his break for engaging in the positive behavior. Screaming would be ignored, while the person was helped to utilize communication to ask for a break.

Reactive strategies are designed to manage a crisis situation and direct instructors in how to respond when challenging behavior does occur. These response strategies are not intended to teach the person any new skills. The teaching comes from all the prior components – antecedent, teaching, coping, and consequence strategies. Reactive strategies are an important part of the plan because it is desirable and necessary to train instructors in proper, safe response techniques rather than rely on improvisation in the heat of the moment. Techniques that have proven to be the most effective and safe *for that individual* are carefully designed and trained. Reactive strategies often include some kind of debriefing for the individual and for the instructors to help everyone get back on track once the incident is over.

Skills Assessment and Individualized Program Development

Another important component of teaching individuals with autism in a residential setting is the creation of an individualized learning plan.

While each person's program is specifically tailored to his or her specific learning needs, there are some learning style characteristics that many people with autism share and which form the basis for a learning program for a person living in a residential setting. Examples of some broad learning characteristics in autism include difficulties with changes in routines and schedules, distractibility, trouble organizing and filtering out relevant information, difficulty with auditory processing, and poor understanding of social cues. It is important to design a learning environment and individualized program that takes these characteristics into consideration while also factoring in the unique learning style of the individual himself.

Components of a residential program that utilize a structured approach to teaching include the strong use of visual supports. Visual supports are those environmental and teaching tools that rely primarily on the visual rather than auditory modality to help teach a person with autism. Visual supports are used to help organize the environment, for example, by labeling drawers and cabinets with pictures and/or words, by arranging furniture and other items to create work and recreational spaces, by color coding and using other visual cues, and by storing and arranging materials in clear plastic containers or designated closets so the contents can be accessed easily. Visual supports are also used to help a person organize, understand, and predict his routine. These take the form, for example, of picture schedules, written checklists, or pictorial or written scripts. One type of visual support that is well suited to a learner with autism is the use of a "first . . . then" map, where a person who is anxious for or motivated to engage in a specific activity can see from pictures or words that once the less preferred task is over, the preferred activity can take place:

- "First clean your bedroom, then play video games."

A consequence chain is another visual tool that helps a learner see and predict the course of events:

- "It's sunny outside: I can go swimming.
- It's raining out: I cannot go swimming: I will go to the gym."

There are dozens of tools and variations that can be created to visually assist a learner to understand his routine, including the use of modeling, pointing, sign language, photographs, objects, video, and even handheld devices and applications.

Lastly, visual strategies are very widely used when teaching skill-building activities. Unlike typical teaching approaches done through presentation of verbal material, visual strategies present information and provide direction more concretely. The spoken word is transitory and fleeting in nature and relies heavily on strong auditory processing skills, whereas visual tools are tangible and enduring. Some examples of visual instructional tools are picture recipes that lay out directions for preparing a meal or picture checklists for grocery shopping. The method of displaying the visual tools is based on the individual's strengths. For some, laying the pictures out sequentially on one long strip is effective; for another, gathering them in a photo album which the learner turns as he completes each step is more suitable. Picture strips may be posted on a wall to assist a person through a step-by-step process, such as brushing one's teeth. Cards or pictures can be kept in a wallet which the learner can pull out as needed. Visual tools are also useful in assisting learners to make choices. Giving the learner two or more concrete visual items to choose from increases the likelihood the person will select the truly preferred item, rather than simply repeating the last item heard, which often happens when people are verbally asked to make a choice.

The teaching method most commonly and effectively used at Benhaven is "errorless learning," a system of teaching a person skills through the use of carefully designed and implemented prompts (Etzel and LeBlanc 1979; McDuff et al. 2001). Skills are broken down into a series of steps, called a "task analysis," and instructors provide prompting designed to help the person complete each step before making an error. Prompts are planfully faded as the learner gains independence at each step. Instructors are trained to provide prompts that are best suited to that individual's needs. A person with strong memory and

visual skills may be successful following a series of pointing prompts – the instructor points to each step in the sequence and the learner responds by engaging in the step. To make a sandwich, for example, the instructor points to the loaf of bread, the learner takes out two slices of bread; the instructor points to the filling, the learner places the filling on the bread; etc. Another learner with greater needs may be more successful with physical prompts, where the instructor guides the person's hands to take out the bread and place it on the plate, take the filling and place it on the bread, etc. Other types of prompts include modeling, gesturing, signing, and, of course, visual supports like photos, pictures, or written instructions. Verbal prompts are not widely recommended for people with autism as they rely too heavily on auditory processing skills and, unlike the other types of prompts, are not easily conducive to fading.

Efficacy Information

The methods described here, including functional behavioral assessment, positive behavioral intervention, structured teaching, and errorless learning, are all widely used in the field of education for people with developmental disabilities and are accepted as effective methods to teach positive behavior and functional skills to those on the autism spectrum (Connecticut State Department of Education 2005). Success of these strategies in a residential setting relies heavily on individualized program planning, consistency of implementation by well-trained and caring direct support staff, and strong oversight of routines and practices by knowledgeable administrative personnel.

Outcome Measurement

Treatment outcomes are measured using a variety of tools. Progress toward reducing negative behaviors and increasing adaptive ones are measured through behavioral data charts that track frequency, duration, and intensity of behavior.

Observational and anecdotal reports are commonly used to track the circumstances under which a behavior occurred. Positive behavior is tracked as well, for example, the frequency with which a person engages in a new, positive behavior or skill and under what circumstances. Mood and behavior may also be assessed via rating scales, for example, by rating a person's affect against a certain set of observable and describable attributes. Data is turned into graphs and charts so that it may be more easily reviewed and analyzed by team members.

Progress in skill acquisition is measured in a variety of ways, for example, by recording the number and type of intervention a person needs to perform the steps of a given activity. Progress may be measured in terms of moving from more severe to minimal prompts (prompt fading), by the reduction of the number of prompts or corrections or by tracking the rate at which steps are performed without intervention.

Less quantitative methods of assessing progress are "quality of life" measures. Does the resident's behavior allow him to engage in activities that bring him pleasure and satisfaction, for example, eating out at restaurants, going to the movies, going to parties, and taking a vacation? Can a resident who formerly needed one-to-one supervision when out in the community now go out with others? Can a resident who used to sit in the back seat of a vehicle because of safety concerns now sit up front with the driver if he prefers? The answers to questions like these provide another equally important and valid measure of treatment outcome.

Qualifications of Treatment Providers

Benhaven's residential program is licensed by the Connecticut Department of Developmental Disabilities and must adhere to that agency's licensing requirements, including requirements in the area of staff training. While not required, many management and administrative staff hold licenses and degrees in areas such as special education, psychology, sociology, and social work. Direct line personnel are not required to hold

specific credentials but receive extensive and ongoing training in autism and teaching methods and philosophies as well as other areas vital for supporting people with disabilities, for example, CPR, first aid, medication administration, and health and safety.

What distinguishes Benhaven's treatment procedures from others is not so much the treatments themselves (which are widely accepted and established approaches and strategies in the field of autism) but, rather, other factors that impact the efficacy of treatment. First of all, program plans are individualized in reality, not just on paper. One of Benhaven's primary treatment philosophies is that there must be an adequate number of well-trained staff to carry out these programs so that residents receive individualized training for skill acquisition and maintenance. For a residential program, Benhaven manages to maintain a remarkably high staff ratio, for example, four staff to six residents during programming time in some settings and in one setting two staff to two residents. Strategies for teaching skills and addressing behavior problems are developed to best meet the needs and suit the learning style of the individual; "one size fits all" is never the approach.

Treatment is also enhanced by the relative longevity and retention of skilled and motivated staff at all levels. Benhaven's residential administration has been in place for between 30 and 40 years; senior management of the seven homes averages over 18 years of employment at Benhaven. Advanced direct support staff constitute over 80% of the total supporters, and the average employment among all direct support staff is well over 5–10 years. In addition, and perhaps most importantly, staff receive ongoing training in groups, in team meetings, and as individuals. Staff performance is monitored through formal and informal observation, with feedback and follow-up provided. All staff, full- and part-time, participate in a staff development process that provides people with an opportunity to receive performance feedback on a quarterly basis. Formal staff evaluations are conducted annually, at which time performance goals are established and reviewed.

Definition

Beta blockers remain essential pharmacological agents in the management and treatment of cardiovascular and endocrine conditions. With little risk of dependence and high target selectivity, recent clinical trials have investigated the efficacy of beta blockers alongside current treatment guidelines for intellectual disabilities and psychiatric conditions

where first-line therapies have failed. Current research suggests that beta blockers may alleviate the motor and psychiatric symptoms present in intellectual disabilities through CNS or peripheral blockade of sympathetic hyperactivity (Connor et al. 1997). As such, beta blockers may act as a potential adjuvant therapy towards the management and treatment of autism spectrum disorders (ASD). Among autistic patients, 30% exhibit anxiety, irritability, and self-injury comorbidities, which previous pharmacological studies targeted for treatment. Recent studies showed beta blockers, particularly propranolol, reduced these comorbidities, sparking new interest examining beta blockers effects on the language and cognitive deficits in ASD (Sagar-Ouriaghli et al. 2018).

Propranolol is a nonselective beta blocker used extensively to treat test and performance anxiety and cardiovascular disease. Unlike other nonselective beta blockers, such as nadolol, propranolol is a lipophilic beta blocker that blocks both the central nervous system and peripheral β -adrenergic receptors allowing for further modulation of cognitive functions (Beversdorf et al. 2002). Furthermore, propranolol is well-tolerated by children and exhibits less unwanted side effects compared to other pharmaceutical agents (Deepmala and Agrawal 2014). Many ASD patients show a decrease connectivity between brain regions involved in language, social, and motor skills (Koshino et al. 2005). Previous studies using propranolol showed ASD children exhibited less anxiety and more social and adaptive behaviors (Ratey et al. 1987). Further analysis demonstrated propranolol's efficacy improving word fluency, conversation problem solving, and conversational reciprocity in ASD patients (Zamzow et al. 2016). In addition, ASD patients show deficits in phonological processing during social and motor tasks (Schmidt et al. 2008). A functional magnetic resonance imaging (fMRI) of 10 autistic patients showed an increase in neuronal networks with propranolol administration during phonological tasks compared to nadolol (Narayanan et al. 2010).

Although social and cognitive deficits remain the focus of autism research, hypersexuality remains a prevalent comorbidity among ASD patients leading to social embarrassment and

repercussions with limited pharmacological interventions available (Deepmala and Agrawal 2014). However, a recent case report of an adolescent ASD patient demonstrated decreased hypersexual behavior upon administration of propranolol (Deepmala and Agrawal 2014). Although the mechanism behind the observed decreased hypersexual behavior remains unknown, current literature suggest that propranolol decreases testosterone and antagonizes serotonin receptors in the brain (Rosen et al. 1988). Overall, these findings encourage future investigations comparing the efficacy of different beta blockers in managing ASD and the mechanism behind their effects.

Bettelheim, Bruno

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Short Biography

A highly controversial figure in the history of autism, Dr. Bettelheim was born in Austria and trained in Art History. His work in history led him to the study of psychology. He became a refugee from the Nazis and moved to the United States.

He eventually moved to Chicago where he became a professor at the University of Chicago (teaching there from 1944 to 1973). He had some psychoanalytic training in Vienna and served, in Chicago, as the Director of the University of Chicago's Sonia Shankman Orthogenic School – a center for treatment of severely disturbed children. He made many claims for successful treatment but did so within the context of claiming that parents were involved in the pathogenesis of autism (a theory now long discredited). His early work on the topic was widely cited, although it is not clear exactly how many children with autism he actually saw. The diagnoses of autism in his patients have also been questioned. His popularization of the concept of the “refrigerator mother” traumatized a generation of parents who were told they were responsible for their child's autism. Questions were raised about possible plagiarism in his scholarly writing and the validity of his work.

Better Outcomes and Successful Transitions for Autism (BOOST-A) Program, The

Megan Hatfield, Marita Falkmer and Marina Ciccarelli
School of Occupational Therapy, Social Work and Speech Pathology, Curtin University,
Perth, WA, Australia

Definition

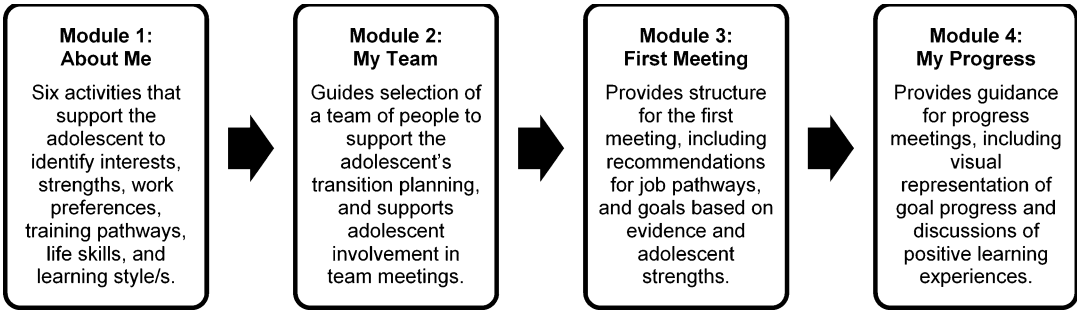

The Better Outcomes & Successful Transitions for Autism (BOOST-A™) is an autism-specific,

web-based program that aims to prepare adolescents on the autism spectrum for the transition from high school to further education, training, or employment. The BOOST-A™ supports adolescents on the autism spectrum to develop career pathways and set goals that enhance their employment-readiness skills. The program consists of four modules, as outlined in Fig. 1.

Module 1, *About Me*, supports career awareness by engaging the adolescent in the following six activities:

- “Interests”: The adolescent completes a questionnaire and is provided with a summary of their key areas of interest related to employment.
- “Strengths”: The adolescent reflects on their areas of strength in the fields of technology, science, physical activities, and arts.
- “Work Preferences”: The adolescent considers the types of work environments they might prefer. They explore factors such as sensory input (e.g., noise and movement), social interactions, and task routines.
- “Training after School”: The adolescent states their preferred post-school training pathway. For example, on-the-job training or an apprenticeship; a vocational training center; or tertiary education at university or college.
- “My skills”: The adolescent explores their current level of performance in activities of daily living, and their participation in community activities.
- “Learning Styles”: The adolescent describes their preferred learning style, which may be one or more of the following: reading, writing, hearing, seeing, or doing.

Module 2, *My Team*, supports the adolescent and their caregiver to identify people who might be best placed to participate in their transition planning, asking them to come together to form a team. In addition, this module provides potential strategies for the adolescent to contribute as actively as possible to the team meetings in a way that they feel comfortable with, as this has been shown to promote increased self-determination (Hendricks and Wehman 2009; Martin and Williams-Diehm 2013).

Better Outcomes and Successful Transitions for Autism (BOOST-A) Program, The, Fig. 1 Description of the four modules of the program

Module 3, *First Meeting*, involves a team meeting that keeps the adolescent at the center of all decision-making. The program provides recommendations for job pathways that leverage the adolescent's strengths. The team decides on a few pathways on which to develop goals. For each goal, the team identifies the actions needed, people responsible, and timeframes for completion. Goals are suggested by the program and encourage the adolescent to gain real-life experiences; e.g., acquiring a part-time job, doing a work experience, finding a mentor, getting more information about potential careers, and developing life skills.

The fourth module, *My Progress*, is completed at subsequent team meetings. The team reflects on the progress toward each goal, and amends and updates the goals and job pathways, as needed. This module encourages the development of resilience through positive reflection, guiding the adolescent to reframe challenging experiences as opportunities for development, rather than failures. Since the program is designed to build self-determination, the adolescent is encouraged to increase their level of involvement at each subsequent meeting. The aim is that the adolescent will eventually lead the meetings and experience a greater sense of control over their plans for the future.

Historical Background

Adolescents on the autism spectrum have numerous strengths; however, many have

difficulty transitioning to post-school employment or higher education (Australian Bureau of Statistics 2012). Furthermore, many people on the autism spectrum are often underemployed or in positions that do not reflect their education level or abilities (Hendricks 2010; Müller et al. 2003). There is increasing recognition of the many strengths people on the autism spectrum bring to the workplace, including low absenteeism, reliability, and excellent recall for information on topics related to their special interests (Mottion 2011; Hillier et al. 2007; Hagner and Cooney 2005). Transition planning enhances post-school outcomes in adolescents with disabilities (King et al. 2005; Wei et al. 2016), but most existing transition planning programs are not autism-specific and may not meet the needs of adolescents on the autism spectrum. Therefore, the current program was developed specifically for adolescents on the autism spectrum to improve transition planning outcomes for this group.

Rationale or Underlying Theory

The program was developed based on three frameworks: self-determination theory, a strengths-based approach, and a technology-based approach. Adolescents with high self-determination are more likely to have post-school employment (Test et al. 2009). The strengths-based approach capitalizes on an individual's expertise and special interests to enhance performance and promote changes in self-determination

(Patten Koenig and Hough Williams 2017). Technology-based interventions are effective in improving outcomes for people on the autism spectrum in areas such as communication, social skills, and emotional recognition (Grynszpan et al. 2014).

Goals and Objectives

Two pilot studies (Pilots A and B) were conducted to determine the feasibility and acceptability of the program (Hatfield et al. 2017b). The effectiveness of the program was then determined in a quasi-randomized controlled trial (RCT) (Hatfield et al. 2016; Hatfield et al. 2017a). Finally, a process evaluation identified the enablers and barriers related to using the program (Hatfield et al. 2016, 2018). The process evaluation involved collecting qualitative and quantitative feedback from the intervention group participants in the RCT.

Treatment Participants

Pilot A consisted of six adolescents on the autism spectrum who trialed the program with their parents and the professionals in their team. Pilot B obtained the feedback from 88 allied health professionals via an online survey. Participants in the RCT and process evaluation were 94 adolescents on the autism spectrum from Australia. The intervention group participants ($n = 49$) received the program and the control group ($n = 45$) participated in usual transition planning practices at their school.

Treatment Procedures

Participants were screened for eligibility and allocated to groups using an alternate allocation method. Outcome measures were completed on enrolment and then 12 months post-intervention, to allow the participants to complete all modules of the program and make progress on their transition planning goals. Outcomes

included self-determination, career planning and exploration, quality of life, environmental support, and domain-specific self-determination. Data were collected from parents and adolescents. Curtin University Human Research Ethics Committee and relevant school sectors provided ethics approval. All participants aged 18+ years provided informed consent and adolescents provided informed assent. For the RCT, normality of the data was determined using the Kolmogorov-Smirnov test. Effectiveness was determined using the independent samples t-test and/or Mann-Whitney U test. An intention-to-treat approach was used, along with the last observation carried forward method.

Efficacy Information

Results from the pilot studies indicated that the program was an acceptable and feasible program (Hatfield et al. 2017b). Modifications to the program were made based on the feedback from participants. Changes included the conversion to a web-based program to improve the usability of the program; a reduction in the content length of the modules; and enhanced use of visuals, such as videos and graphics.

The RCT results indicated significant differences in favor of the intervention group in three areas: (i) opportunity for self-determination at home (parent report); (ii) career exploration (parent and adolescent report); and (iii) transition-specific self-determination (parent report) (Hatfield et al. 2017a). There were no significant differences between groups for the summary scores of the remaining outcomes.

Results from the process evaluation indicated that the program enabled adolescents on the autism spectrum to feel empowered because of the strengths-focus of the program (Hatfield et al. 2018). The program supported parents and adolescents to overcome inertia and take action by providing a structured process to follow, and providing new insights into potential career pathways. Participants were less likely to report benefits from using the program when they did not have a “champion” in their team. The

champion was typically a parent or professional taking charge and moving the transition planning process forward.

Outcome Measurement

The primary outcome of the RCT was self-determination, measured by the AIR Self-Determination Scale (AIR). The four secondary outcomes included: (i) Career planning and exploration, measured by the Career Development Inventory – Australia – Short Form (CDI-A); (ii) Quality of life, measured by the Personal Wellbeing Index-School Children (PWI-SC); (iii) Environment support, measured by the Learning Climate Questionnaire (LCQ); and (iv) Domain specific self-determination, measured by the Transition Planning Objectives Scale.

Qualifications of Treatment Providers

The program is appropriate for use by trusted adults who support the adolescent in transition planning including parents, educators, and allied health professionals, such as occupational therapists, psychologists, and speech pathologists. No formal training, certification, or level of qualification is required.

Introduction

Standardized diagnostic tools are critical in terms of assessing Autism Spectrum Disorder (ASD). There is an increasing interest in how culture, sex, social economic status, and other factors affect the performance of concurrent gold standard instruments for the purpose of identifying autism spectrum disorder (ASD). While the performance of, for example, the Autism Diagnostic Observation Schedule (ADOS) (Rutter et al. 2012) and the Autism Diagnostic Interview (ADI-R) (Rutter et al. 2003) performs well in identifying individuals suspected of ASD, and especially when used to complement each other, little is known on the performance of the ADOS and the ADI-R in different cultures, ethnicities, and between sexes. Most of the instruments created for the purpose of identifying ASD are created and validated in the USA and Europe. However, they are often translated into a large range of languages for use in different cultures and ethnicities, without conducting validation studies of the instruments. As a result, it could be discussed how culture, ethnicity, sex, and the translation itself affect test performance of instruments. Even considering how instruments work between sexes are rarely examined in validation studies of instruments. In terms of parent report, it is likely to believe that culture could affect how parents regard various elements of behavior and development, and how

BG-II

► Bender Visual-Motor Gestalt Test II

Bias

► Measurement Error

parents rate their boy or girl in terms of endorsement of, for example, behaviors or development.

Current Knowledge

While we do believe that some of the issues raised could potentially bias diagnostic instruments, little has been reported on ASD-specific diagnostic instruments in terms of potential biases and test performance (Volkmar et al. 2014). A recent study by Vanegas et al. (2016) revealed that the sensitivity and specificity of the ADI-R were moderate, but lower than previously reported values. However, currently we have little information on test performance from different cultures, ethnicities, taking sex also into consideration. Behavioral, developmental and temperamental differences could ultimately affect the performance of screening and diagnostic instruments (Dworzynski et al. 2012; Macari et al. 2017; Øien et al. 2017). In terms of culture, research has revealed cross-cultural prevalence differences (Elsabbagh et al. 2012), and culture is regarded to have a great impact on how ASD is perceived, diagnosed, and treated across cultures (Volkmar et al. 2014). In the western world, early diagnosis is regarded as paramount for early intervention and access to services. It is not sure to what extent, but a diagnosis of ASD could in other cultures impair the access to treatment and services. A great example of how ASD symptomatology could be affected by culture is found in eye contact. As impairment or atypicalities in eye contact is regarded as a core symptom of ASD, avoiding eye contact in some eastern cultures are regarded as appropriate and polite (Volkmar et al. 2014). Non-autism-specific research, among the Sami population of Norway (ethnic minority), revealed that disorders such as ASD and other mental health disorders were not prevalent as in the larger non-ethnic majority of Norway (Nergård 2006).

Future Directions

As there is a pressing need to understand how culture, ethnicity, sex, and other factors affect test performance of a range of different diagnostic

instruments, it is necessary to focus on implementation of validation studies when diagnostic instruments are translated. While translating and back translating is regarded as necessary, translations of instruments can still incorporate wording or translations that might not be suitable for the given culture, ethnicity, or language. Future studies should also examine the performance in sex separately, aiming at exploring if there are different sensitivity and specificity for males and females, respectively. One solution for future research should be to conduct meta-analyses of test performance of the various diagnostic instruments across cultures, ethnicities, and social economic statuses, taking sex into consideration. This could show if the diagnostic instruments perform differently in different conditions, and it could also indicate in which areas the discrepancies arise from. Increasing knowledge on how to identify ASD in third world countries and cultures is of highest importance, and current diagnostic instruments are often too expensive for many cultures and countries. Focusing on the development of community-based identification of ASD in areas with limited resources and utilizing less comprehensive, but culture-sensitive instruments could potentially decrease differences in prevalence and differences across cultures.

Bilingualism and Language Development in Children with Autism Spectrum Disorders

Ana Maria Gonzalez-Barrero¹ and Aparna Nadig²

¹Department of Psychology, Concordia University, Montreal, QC, Canada

²School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada

Definition

Bilingually exposed children with autism spectrum disorders (ASD) are those who are exposed to two languages from early ages. These children are typically being raised in bilingual families and/or bilingual communities. Bilingualism is a multidimensional characteristic that is influenced by multiple factors such as sociolinguistic context (e.g., majority or minority language), age of acquisition, and amount of exposure or usage (for children) or proficiency (for older children and adults), among others (Surrain and Luk 2017). Additionally, socioeconomic differences

are linked to bilingual status in some contexts. These factors need to be kept in mind when interpreting and comparing research findings (Kay-Raining Bird et al. 2016).

Historical Background

Parents of children with ASD are commonly advised to use only one language when interacting with their children. This often stems from beliefs that bilingualism might be too challenging or confusing for the child and hinder his/her language development (Yu 2013). However, evidence does not support this claim (for reviews see Drysdale et al. 2015; Lund et al. 2017). Research with children under age 6 has repeatedly shown no additional language delays caused by bilingual exposure. Importantly, in the long term, bilingualism can provide social and vocational advantages. For children from bilingual families and communities, it also provides opportunities to maintain familial bonds (Yu 2013) and rich social and linguistic input (Hudry et al. 2018). In situations of highly proficient bilingualism, it may even provide advantages in some executive function skills (Gonzalez-Barrero and Nadig 2017, 2019b; Nadig and Gonzalez-Barrero 2019).

Current Knowledge

Bilingual Language Development in Toddlers and Preschoolers

Research with toddlers and preschool bilingual children with ASD has shown that these children reach language milestones, such as first words and onset of first sentences, at a similar age relative to their monolingual peers with ASD (Hambly and Fombonne 2012; Ohashi et al. 2012; Valicenti-McDermott et al. 2013). Furthermore, their early vocabulary and communication skills develop at a similar rate to that of children with ASD exposed to only one language (Dai et al. 2018; Ohashi et al. 2012; Petersen et al. 2012; Reetzke et al. 2015). Most studies on bilingualism and ASD including children of this age have relied primarily on parent report, which is a valid measure to use early in

development (e.g., Hambly and Fombonne 2012; Reetzke et al. 2015). However, there is a lack of studies examining the language development of school-age bilingual children with ASD. It is important to extend investigations to this older age group as more sophisticated language skills are developed during the school years when language is used as a tool for learning.

Bilingual Language Development at School Age

Only a few studies have directly examined the language skills of school-age bilingual children with ASD (Gonzalez-Barrero and Nadig 2018, 2019a; Meir and Novogrodsky 2019). Importantly, unlike early development, at school age it is well established that typically developing monolinguals outperform bilinguals on standardized language tests administered in one language (Bialystok et al. 2010), which is linked to bilinguals' language exposure being split between languages (Thordardottir 2011).

How do bilingual children with autism, without intellectual disability, fare at school age? Gonzalez-Barrero and Nadig (2019a) assessed the vocabulary and grammatical skills of 13 bilingual and 13 monolingual school-aged children with ASD (age range 5–10 years). Children were recruited in Montreal, Quebec, Canada, a multicultural city where the use of French and English is a common practice and both languages are official languages of the country. Children were speakers of French, English, Spanish, or the combination of two of these languages. To qualify as bilingual in this study, children had to meet a rigorous three-step criterion including amount of exposure above 20% to two languages, proficiency judgments from parents, as well as completion of tasks in both languages. Bilinguals and monolinguals did not differ with respect to chronological age, nonverbal IQ, maternal education, dominant language, or autism symptoms, and a similar percentage of children in each group had language impairment. Standardized tests of vocabulary and grammar were administered to compare the performance of the bilingual children with ASD relative to their monolingual peers with ASD. Results concerning receptive vocabulary

skills in the bilingual children's dominant language showed a trend where monolingual children exhibited higher scores relative to bilinguals. Yet, most of the bilingual children with ASD performed within the average range of the test (within 1 SD above or below the test mean). Results from the expressive grammatical test mirrored those found for vocabulary skills; there were no significant differences between the bilinguals' dominant language scores and those of the monolingual group, although there was a tendency in the bilingual group to score below the average range on this measure. These findings demonstrate the same patterns found in typically developing bilinguals (Bialystok et al. 2010) and highlight the key role that amount of language exposure plays in child language abilities, in autism (Gonzalez-Barrero and Nadig 2018) as in typical development.

Hoang et al. (2018) elicited short narratives in a picture sequencing task from a subsample with similar characteristics to the participants just described ($n = 20$, including 5 bilinguals and 5 monolinguals with ASD). As reported in Gonzalez-Barrero and Nadig (2019a), monolinguals had higher receptive vocabulary scores than bilinguals. Yet, when using language functionally to tell a narrative, bilinguals produced significantly more utterances than monolinguals. With respect to narrative skills, bilinguals and monolinguals did not differ in macrostructure (e.g., sequencing of events and coherence), microstructure (e.g., use of referential terms and conjunctions), or elaborations (e.g., sound effects, character speech). Baldimtsi et al. (2016) used a similar study design to examine narrative production in Greek-speaking bilinguals and monolinguals with and without autism and found that bilingual children with ASD outperformed monolinguals with ASD in some narrative skills. Though preliminary given very small sample sizes, these converging findings suggest that lower standardized language test scores in bilingual children with autism do not reflect a reduced ability to use that language functionally.

This body of work provides information to clinicians working with this population as it demonstrates that many children with ASD can

become bilingual when adequate language exposure is provided (Gonzalez-Barrero and Nadig 2018). Additionally, in contrast to language development during the early years, it is expected that at school age bilinguals will underperform relative to their monolingual peers on standardized language tests, which calls for caution when assessing bilingual children with ASD using monolingual norms (Thordardottir 2015).

Future Directions

With the increasing rate of bilingualism around the world (Surrain and Luk 2017), more research is needed to better understand and describe the language development trajectories of children with ASD being raised in bilingual families and societies. Although there is a growing interest in bilingualism and autism, and some studies have recently been conducted examining the narrative and syntactic abilities in this population (e.g., Hoang et al. 2018; Meir and Novogrodsky 2019), more studies are needed in language domains such as phonology and pragmatics, as well as comparing different contexts of bilingualism.

A review indicated that many practitioners would like to support bilingualism in children with developmental disabilities when relevant for families but that the lack of bilingual specialized services and educational opportunities is a major obstacle (Marinova-Todd et al. 2016). Baker et al. (2018) offer a potential solution through dual immersion educational programs for children with autism, and with respect to how a child's heritage language can be incorporated in therapy, see ► [“Heritage Language Use for Intervention in Autism”](#). The development of bilingual services and research evaluating them is a critical area for future work.

In sum, the available evidence suggests that bilingualism is a possible outcome for children with ASD and that bilingually exposed children with ASD show globally similar language development trajectories to their monolingual peers with ASD. Thus, parents of bilingual children should be encouraged to use the language in

which they can better interact with their child, which could facilitate the delivery of parent-implemented interventions (Lim et al. 2019) and allow parents to provide quality input that supports language development.

Biological Motion

Martha D. Kaiser

Child Neuroscience Laboratory, Yale Child Study Center, New Haven, CT, USA

Synonyms

Human or animal motion

Definition

Biological motion refers to the movements of humans or animals including eye, face, and full body motion. Typical observers exhibit robust sensitivity to biological motion cues provided by other people. However, disrupted sensitivity to biological motion, at the behavioral and neural level, is emerging as a hallmark of autism

spectrum disorders (ASD). The lack of tuning to such socially relevant information may reflect some of the pathognomic social deficits associated with ASD.

Biomarker Research in Autism Spectrum Disorder

Talena C. Day and James C. McPartland
School of Medicine, Child Study Center, Yale University, New Haven, CT, USA

Definition

A biological marker (biomarker) is defined as a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (Biomarkers Definitions Working 2001). Although the term biomarker is often associated with biological processes, many data modalities can be used to objectively measure relevant processes, such as genes, metabolites, brain structure and function, and overt behaviors. In fields like oncology, biomarkers have been categorized into

meaningful subtypes, and similar efforts to classify biomarkers in neuropsychiatry are in progress (Davis et al. 2015; McPartland 2016). Through meaningful subtypes, biomarkers can serve a multitude of purposes in autism spectrum disorder (ASD) research and treatment.

Diagnostic biomarkers are discrete, and objective measures of whether or not an individual has ASD and their identification have been a long-standing objective in the field. Diagnostic biomarkers should not overlap with other conditions, reflected in the sensitivity and specificity of biomarkers (Davis et al. 2015).

Screening biomarkers measure diagnostic risk status and potentially measure processes prior to observable behavioral symptoms. Screening biomarkers would allow for intensive early intervention for individuals which have been shown to improve the prognosis of ASD (Dawson et al. 2010; Estes et al. 2015; Lovaas 1987; Smith et al. 2000).

Stratification biomarkers determine meaningful subgroups of individuals to predict or evaluate treatment (Loth et al. 2016a). Stratification biomarkers, for example, may indicate a group of children with ASD who may be likely to respond to a specific treatment.

Early efficacy biomarkers indicate whether a treatment is altering targeted symptoms or the processes underlying those symptoms (McPartland 2016). In autism, an early efficacy biomarker may reveal symptomology changes from a treatment before they are observable in clinical observation or caregiver report, the current measures used in clinical trials of ASD.

Target engagement biomarkers measure whether an intervention is affecting the intended process (Zhao et al. 2015). For example, in autism, a target engagement biomarker might assist in determining whether a specific medication is affecting neural activity in the intended brain region.

These biomarker subtypes strive to improve the understanding of autism and foster precision-medicine approaches in the diagnosis and treatment of autism (Varcin and Nelson 2016). Determining which biomarker subtype is under research will guide study designs and impact future applicability. Nevertheless, before the

field can reliably utilize biomarkers, key challenges in the identification of biomarkers must be addressed in future study designs.

Historical Background

Biomarker identification and validation in ASD, a condition characterized by two domains of core symptoms, including impairments in social communication and presence of restricted and repetitive behaviors (American Psychiatric Association 2013), hold promise in subtyping the heterogeneous neurodevelopmental disorder and guiding personalized treatments. In other biomedical fields, such as oncology, biomarkers have been successfully implemented to inform personalized treatments as well as measure processes involved in the diagnosis, prognosis, and prevention of various cancers (Nalejska et al. 2014). For example, treatments for different forms of cancer are based on specific genetic mutations (Kalia 2015).

Despite significant biomarker discovery efforts in ASD, biomarkers are not yet readily applied in the treatment and diagnosis of ASD. Clinical judgment of observable behaviors remains the primary clinical tool applied in ASD. The diagnostic criteria, as outlined in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, consist of a checklist of behaviors in which a tally of symptoms across domains constitutes as a diagnosis (American Psychiatric Association 2013). The strongest and most reliable diagnostic tools include a parent interview (Lord et al. 1994) and play-based observational assessment (Lord et al. 2012). Furthermore, clinicians determine the best course of treatment and prognoses based on the results of these standardized behavioral assessments and subjective evaluation. Outcomes, from the individual level to multisite clinical trials, are often reported by parent and teacher report or behavioral observation. The applications of these methods have significantly advanced autism, used interchangeably with ASD, research, and these clinical tools can be administered reliably. Nevertheless, the nature of these methods remains remarkably similar to the methods used by Asperger (1944) and Kanner (1943) decades ago.

Biomarker discovery for autism remains in its infancy. The first steps in identifying potential biomarkers are operationalizing the definition for the term “biomarker” and describing various subtypes. Challenges to biomarker research must be highlighted so that future research endeavors can determine the best course of action to address them in study designs. Currently, national and international studies are underway and address many of these challenges to biomarker research, and studies with large cohorts show promising signs of biomarker discovery in ASD. Future studies must consider the objectivity, sensitivity, and scalability of the methodologies used to measure biomarkers to ensure a large public health impact.

Current Knowledge

Specificity of Biomarkers

It is well-established that autism is an extremely heterogeneous disorder containing a large variation in core diagnostic features and associated characteristics, such as cognitive and language ability. Therefore, the search for biomarkers of ASD may prove elusive for potential underlying etiologies. Instead, a more effective approach may be to research potential biomarkers in relation to specific functional processes or symptom indices, as outlined by the Research Domain Criteria approach (<http://www.nimh.nih.gov/research-priorities/rdoc/>), rather than in relation to diagnostic status. Many features present in autism are found in other disorders; for example, repetitive and restricted behaviors are present in obsessive compulsive disorder, and social dysfunction is present in schizophrenia spectrum disorders. Often, treatment goals are centered around variation in a specific area as opposed to diagnostic status more broadly. Biomarkers that measure changes in specific functional domains may prove extremely useful in these cases as opposed to biomarkers measuring diagnostic status.

Individual Versus Composite Biomarkers

Generally, biomarker studies in ASD and other neurodevelopmental disorders focus on utilizing

a specific measure as a biomarker. For example, a study may focus on activation in a specific brain region associated with social behavior. Yet, the complexity of biological processes that give rise to social behavior, as well as the potential for compensatory mechanisms within these processes, and the well-known heterogeneity in autism complicate the potential utility of a single biomarker. It may be necessary to develop biomarkers reflecting multiple measures. An individual's profile as measured through a composite from multiple biomarkers, either within one data modality or across data modalities, may provide more relevant information for prognoses and treatment compared to a single biomarker.

Developmental Considerations

Autism is a developmental disorder wherein early-life symptoms influence experience as well as experience-expectant biological processes (Dawson et al. 2005). Different biological systems may have varying developmental trajectories. Therefore, in individuals with ASD, the patterns of brain activity represent an interplay between early-occurring neural atypicalities and subsequent developmental sequelae. Consequently, biomarker studies conducted at different developmental points may result in disparate findings. A key factor in biomarker discovery in autism will be understanding biomarkers across development. To address this factor, biomarker research must be conducted with sufficiently large samples to analyze developmental effects or performed in tightly developmentally constrained studies.

Differences At the Group and Individual Level

In autism research, and neurodevelopmental disorders more generally, studies report findings as differences in means between groups of individuals. These findings often reflect a shift in the distribution of values between the groups on a biomarker parameter. Thus, there is little information about the biomarker at the individual level unless the value of the biomarker is true for every individual with ASD. Advancing translational goals of biomarkers requires designing studies to evaluate effects at the individual level or individual variation on specific characteristics. Through

these study designs, biomarkers may, at the individual level, provide relevant information.

Current Efforts in Biomarker Discovery

While significant challenges to biomarker discovery in ASD are present, many are addressed through studies developed by collaborative consortia. Researchers are working together to develop protocols for multiple data modalities to identify biomarkers in autism and disseminate these methodologies. Through large cohorts or longitudinal designs, oftentimes both, these studies address many of the challenges to biomarker research in ASD and offer the first opportunities to review biomarkers in autism with sufficiently large sample sizes.

The largest ongoing effort toward autism biomarker measure development is the European Autism Interventions – A Multicenter Study for Developing New Medications (EU-AIMS) Longitudinal European Autism Project (LEAP). The multisite, multidisciplinary study aims to discover stratification biomarkers for ASD. Throughout the study, participants are characterized through their symptom profile, comorbidities, quality of life, adaptive functioning, neurocognitive profile, brain structure and function, biochemical biomarkers, prenatal environmental risk factors, and genomics (Loth et al. 2016b). For this study, validation of biomarkers will be carried out similar to other biomedical fields in which biomarkers are used for specific clinical practice (Lee et al. 2006). Subgroups will be divided through a priori definitions or through data-driven approaches. The protocols will be shared with international research groups to determine reproducibility (Loth et al. 2017).

The Autism Biomarkers Consortium for Clinical Trials (ABC-CT) is a US-based multisite study working in collaboration with EU-AIMS for similar purposes. The ABC-CT is dedicated to utilizing objective approaches to develop reliable measures of social-communicative behaviors in children with autism (www.asdbiomarkers.org). The longitudinal study collects electrophysiological, eye-tracking, and video-tracking data as well as comprehensive characterization of individuals through parent interviews, behavioral

observation, and parent questionnaires at three points over a 6-month period. Additionally, DNA samples are collected from the participants with autism and their biological parents for future genetic analysis. Ultimately, the study is designed to create an infrastructure which will readily transfer into research and treatment areas, such as clinical trials, with tools that will allow for objective and predictive measurements of how individuals with ASD will respond to treatments.

In contrast to these studies oriented toward biomarkers for use in clinical trials, the Infant Brain Imaging Study (IBIS) Network seeks to develop screening and diagnostic biomarkers. The study collects longitudinal MRI data at ages 6, 12, and 24 months from infants who have an older sibling with autism thus have an increased risk for developing autism themselves (Shen et al. 2017). It has already delivered promising results, as elevated extra-axial cerebrospinal fluid (EA-CSF) at 6 months of age predicted the diagnosis of toddlers at 24 months of age where the infants with most severe autistic behaviors at 24 months had the highest EA-CSF volume. This converged with findings from an earlier study with EA-CSF (Shen et al. 2013). The longitudinal study design deepened the developmental understanding of EA-CSF in typical and atypical development, and the automated segmentation algorithm used has the potential to translate to many settings (Pelphrey 2017).

The consortia address many of the challenges to biomarker identification in autism through their study designs. By establishing multisite studies, biomarker measures can be evaluated with sufficiently large cohorts, developmental effects can be examined through large cohorts and longitudinal design, and the feasibility of translating these measures to a larger scale can be assessed.

Future Directions

The efforts in biomarker research are moving toward earlier identification and precision-based treatments of ASD while simultaneously deepening our understanding of the disorder. The success of proposed biomarkers, however, is dependent

on the translational impact of the technologies used to measure these biomarkers. In order to implement biomarker research goals, the biomarker measures must be objective, sensitive, economical, and scalable. Here, electrophysiology is used as an example addressing the aforementioned criteria.

Applicability

Methods that are useful in a large functional range, such as individuals with intellectual disability, and developmental range, as early as infancy, are well suited for future biomarker research. Electrophysiology requires minimal instructions with a straightforward application. Generally, the participant is only required to tolerate sensors on their skin. Artifacts due to movement during a session recording are specific to trials which can be removed from the data or corrected to preserve the integrity of the recording.

Objectivity

Methodological rigor in defining biomarker parameters when compared to other methodologies like behavioral methods will be critical for future research. Consistent data collection across multiple locations is possible through identical equipment and experimental paradigms without the need for developing clinician reliability.

Sensitivity

Electrophysiological measures, for example, can potentially measure processes relevant to biomarker discovery more sensitively than behavioral methods. These recordings may delineate processes that either may never be present in behavior or not present in behavior yet. Many of the features that characterize the ASD diagnosis are not observable until the second year of life; therefore, methods that sensitively index these processes may elucidate atypical processes before overt behaviors are displayed.

Cost and Scalability

Electrophysiological methods are an extremely cost-effective way to measure biological processes; thus prohibitive cost is not a factor compared to other biological assays. Large-scale

implementation with electrophysiological recordings would readily translate into the current healthcare system since these facilities already exist. Psychophysiological methods offer both low cost and widespread availability necessary to utilize biomarkers on a public health level.

Conclusion

Biomarker research has made considerable strides in the last decade. Long-term investments have been made in the hopes of discovering translatable, practicable biomarkers. As the field of biomarker research moves forward, researchers must ascertain the appropriate biomarkers to pursue and whether it is more advantageous to examine processes dimensionally or examine diagnoses categorically. While there are many challenges to biomarker research in autism, identifying and addressing these challenges will increase the ability to discover applicable biomarkers. Large-scale efforts such as the EU-AIMS LEAP and ABC-CT demonstrate collaborative efforts that should have the power to detect modest effect sizes and promise to disseminate the methodologies used to translate these potential biomarkers to other settings. Due to the current efforts in the field, biomarkers may soon be informing individualized treatment plans and implemented in multisite clinical trials and deepening our understanding of autism.

Definition

Birth is a crucial event in life. The transition from the uterine status to the outside world is a very stressful occasion for parents but also for the newborn child. In retrospect, many parents will impute developmental deviances to a poor start in life. Thus, birth and perinatal complications and the first week of the neonate have been the focus of many research aimed to determine if factors involved with birth and start of life play a role in the etiology of autism.

Definitions

- Birth: the transition from intrauterine life to life outside. This includes the vaginal pathway or the extraction through a so-called caesarian operation.
- Complications: any deviance from normal physiology around the birth (perinatal period).
- Perinatal period: an interval extending from the 28th week of gestation until the 28th day after birth.
- Apgar score: simple repetitive method introduced by Virginia Apgar in 1952 to assess the health of a newborn baby – appearance (skin color), pulse (heart rate), grimace (reflex irritability), activity (muscle tone), and respiration. The five criteria are given marks ranging from 0 to 2. 0 is absent of highly disordered and 2 is fair and normal. Thus, the scale ranges from 0 to 10. It is mostly scored 5 and 10 min after birth. 7–10 is considered normal, 4–7 fairly low, and under 3 critically low.

Historical Background

Direct injuries following forceps extractions or acute termination can cause massive damage to the brain of a neonate, with palsy and severe developmental hazards as consequences. These dramatic circumstances have not been related to the emergence in later life of any form of psychopathology. But over the years, subtle deviances at birth (low Apgar scores, respiratory distress, hypoglycemia, or hyperbilirubinemia after 5–7 days) have been associated with developmental disorders such as attention deficit hyperactivity disorders of autism.

When taking the developmental history in parents of children with developmental disorders, one is often struck by the emphasis put on perinatal hazards. These retrospective recollections are not always reliable. Yet they illustrate how much value is given to the condition of the child just after birth as a potential cause of later disorders. Thus, methodologically retrospective data must be distrusted. In this item, the evidence for associations between birth complications and autism will be reviewed from methodologically sound studies.

Current Knowledge

Gardener et al. (2011) carried out a comprehensive meta-analysis to evaluate the perinatal and neonatal risk factors for autism. After a PubMed, Embase, and PsycINFO search, 60 methodologically sound studies (out of 124 published until 2007) could be retained for a thorough meta-analysis of the possible causal relationship between the occurrence between perinatal and neonatal complications and autism. Since then, only five studies were published to date, implying that the Gardener et al. meta-analysis gives a good summary of the current knowledge with regard to peri- and neonatal factors that are associated with an increased risk for autism. This formulation is of great importance because peri- and neonatal factors appear to be by no means specific for any kind of psychopathology, thus pointing towards a multicausal heterogeneity already hypothesized by Bolton et al. (1997).

But the results from series of well-conducted studies clearly show that there are factors that have no association with autism and others that show a positive association with the occurrence of autism later in life:

Factors that show *no association with autism* are the following: premature rupture of membranes, delayed labor, loss of amniotic fluid on the day before delivery, analgesia during labor, green [meconium holding] amniotic fluid, acidosis ($\text{pH} < 7.2$ in the umbilical cord, shoulder dystocia, near-dead baby, “blue baby,” hypoglycemia, hypocalcemia, infantile vomiting, intracranial hemorrhage, macrocephaly, abnormal fetal cardiac activity, assisted vaginal delivery, post-term birth, a high birth weight, and incubator use! Finally, neither preterm birth nor Cesarean delivery reached statistical significance.

Factors that *do show a significant increase of the risk for autism* are the following: abnormal presentation in general, breech presentation, umbilical cord complications (prolapse, cord wrapping around the neck), multiple birth, (very) low birth weight, small for gestational age, fetal distress, Apgar scores low after 5 min, birth injury or trauma, congenital malformations, meconium aspiration, neonatal anemia, ABO or rhesus incompatibility, and hyperbilirubinemia. There are also two factors that are not related directly to the condition of the child but enhance the risk for autism and those are: maternal bleeding and season of birth (with two high-risk periods, namely, children born in March and in the late summer (August and September)).

Yet, from the discussions around birth complications as a risk factor for autism, it appears clearly that they cannot be perceived independently from earlier prenatal factors. Factors such as advanced age of both mother and father, but also an autistic condition in the offspring as a result of genetic and early embryo-environment interplay early in gestation (viral infections, drugs, etc.), suggest that the birth complications are more the result of prenatal factors that are the cause of autism later on. According to the classic Bolton et al. (1997) study on the “shared risk hypothesis,” this shared risk hypothesis is also supported by the Zwaigenbaum et al. studies

(2002) that show more composite prenatal, perinatal, and neonatal adversity among both affected children and unaffected siblings in families with a high loading for the broader autism phenotype.

Future Directions

In order to fully understand the impact as a risk factor of birth complications on the increased risk for autism, longitudinal studies, starting well before birth like the ABC study in Norway of Generation R, are needed in order to get a better understanding of the interplay between family genetic-embryonic development-birth hazards and neonatal stress on the risk factors for autism.

effects have been identified in a few studies. One type of birth order effect that has been observed and replicated is a lower nonverbal IQ score in the second child with autism in the family (Lord 1992; Spiker et al. 2001). Another study found that there was an effect of birth order on multiple aspects of autism including repetitive behaviors, phrase speech, social communication, and non-verbal communication (Reichenberg et al. 2007). Finally, in a more recent study general birth order effects were seen where middle births in multiplex families and later births in simplex families were more likely to develop autism (Turner et al. 2011). There are a number of potential reasons for birth order effects, and these include demographic factors such as stoppage in a family after the first child with autism is born, as well as biological factors including paternal age effects, maternal age effects, maternal-fetal genotype incompatibilities, and potential epigenetic effects. The discovery of birth order effects can help guide researchers in their examination of potential risk factors for autism.

Blindness

Therese R. Welch

School of Medicine and Dentistry, University of Rochester Medical Center, Rochester, NY, USA

Definition

The relationship of blindness and autism spectrum disorders (ASD) is complex, and, as a group of prominent researchers had aptly noted, it has been a continuing source of interest and perplexity for researchers and clinicians (Hobson et al. 1999). Central to examinations of the relationship is a collection of behaviors regarded as characteristic of children who are blind, in particular children who are congenitally blind, and children who have profound visual impairment. The collection includes stereotyped and ritualistic behaviors, pronounced limitations of social and communicative competence, delayed and limited symbolic play and language, delayed use and reversals of personal pronouns, echolalia and speech limitations, and difficulties with abstract thinking (Gense and Gense 2005; Perez-Pereira and Conti-Ramsden 1999).

Many of these behaviors also are considered to be characteristic of sighted children who have ASD. Because of the seeming commonality of certain behaviors of children who are blind and children who have ASD, researchers and clinicians have been challenged in understanding the nature of the apparent similarities (Fazzi et al. 2007; Hobson and Lee 2010; Parr et al. 2010). Essentially, the question is whether such behaviors, when demonstrated by blind children, indicate ASD. Blindness literature can offer other hypotheses for what are viewed as autistic-like behaviors in blind children: Careful consideration should be given to sensory and social deprivation, early medical complications, limited motor or physical activities, lack of ability to imitate, lack of a variety of activities, self-regulation, and others (Huebner 1986; McHugh and Lieberman 2003; Warren 1984).

The preeminent challenge for both researchers and clinicians may well be definitively identifying ASD in individuals who have significant vision loss. A major hurdle is the lack of appropriate diagnostic screening and assessment tools for this population. Standards, such as the Autism Diagnostic Observation Schedule (ADOS: Lord et al. 1999, 2001, 2002, 2008) and Childhood Autism Rating Scale (CARS: Schopler et al. 1988; Schopler and Van Bourgondien 2010), which are designed for use with sighted individuals, are heavily weighted with visually based tasks. In assessing blind subjects, some researchers have made modifications to these tools, claiming their clinical utility, although the validity of these modifications has not been tested (Jutley-Neilson et al. 2013; Williams et al. 2014). The absence of measures designed for use with children who have significant visual impairments compounds the difficulties of differentiating autistic-like behaviors from ASD in blind children.

Historical Background

In the field of blindness, the classic writings of Selma Fraiberg are most often recognized as the first reports of autistic-like behaviors in blind

children. In 1964, Fraiberg and Freedman published their observations of a group of blind children, stating that nearly a third of the children had “ego deviation.” Keeler (1958), however, is credited with the earliest report of such behaviors in his study of young children with retrolental fibroplasia (otherwise known as retinopathy of prematurity). Several later studies continued investigation of an association between ASD and specific ophthalmological disorders or certain genetic disorders associated with a significant visual impairment. The most frequently researched diagnoses have included Leber’s congenital amaurosis, optic nerve hypoplasia, septo-optic nerve dysplasia, CHARGE syndrome, and retinopathy of prematurity (Bahar et al. 2003; Chase 1972; Ek et al. 1998; Smith et al. 2005). Researchers, however, are not in consensus regarding the association between a specific ophthalmological diagnosis and ASD (Fraiberg 1977; Hobson et al. 1999; Mukaddes et al. 2007).

Some investigators indicated that congenital blindness predisposed a child to ASD (Brown et al. 1997). As researchers sought a better understanding of the relationship between blindness and ASD, the scope of investigations broadened. The degree of vision impairment in relation to the manifestation of autistic-like features or ASD in children who are blind has been a focus of investigators. Some researchers have claimed that more severe vision loss, especially loss of the ability to distinguish forms, increases the likelihood of autistic-like behaviors (Cass et al. 1994). Cognitive impairment reflected in low IQ scores, as well as other additional disabilities, has also been associated with autistic-like behaviors and ASD in blind children (Brown et al. 1997).

Other studies have examined the roles of sensory deprivation and related environmental factors in contributing to the presence of the autistic-like behaviors and ASD. Some investigators have taken a functional perspective of these behaviors, countering that in most cases, such behaviors are adaptive responses to vision loss (Cass 1998; Mottron and Burack 2001). A later review of studies reported that there were no consistent results regarding the relationship and specific types of ophthalmological diagnoses, the severity

of vision impairment, and the role of associated disabilities (Mukaddes et al. 2007).

Tied to the complexities of identification of ASD in blind children have been questions of prevalence. Reported prevalence rates have varied greatly. The US Centers for Disease Control and Prevention (CDC) conducted surveillance of children with visual impairment in metropolitan Atlanta, Georgia, and determined that approximately 6–7% of the children had co-occurring ASD (Kancherla et al. 2013). Studies have reported up to 30 times greater prevalence of ASD in blind children than in sighted children (Cass et al. 1994; Hobson et al. 1999; Jure et al. 2016).

Current Knowledge

A recent review of 11 studies published from 2000 to 2015 focused on the similarity between visual impairment and autistic traits (Buchart et al. 2017). Findings suggested that the presence of autistic traits, such as limited communication and social interaction, together with repetitive and restrictive behavior does not necessarily warrant a diagnosis of ASD. The authors specifically noted that sample sizes were small, and measures used to diagnose ASD have not been systematically tested on a broader visually impaired population. [It is important to recognize, however, the low prevalence rate of childhood blindness. According to a US survey, it is the least prevalent, 0.13%, of all developmental disabilities (Boyle et al. 2011)]. The authors also expressed concern that some studies had adapted standardized autism diagnostic measures, thus undermining their validity and reliability.

Debates have continued regarding the nature of autistic-like behaviors in children with significant vision loss. Andrews and Wyver (2005) have held that blind children who also display such behaviors should be viewed as having specific features rather than being on the autism spectrum. The authors questioned whether these behaviors of blind children are characteristic of *true* ASD or a different developmental pathway. Hobson and Lee (2010) also referred to a distinctive

underlying pathway for blind children's features that seem characteristic of ASD. They, in fact, termed the features as being *quasi*-autistic and suggested the clinicians hold back from the designation of *ASD*. Williams et al. (2014) reported that some behaviors suggestive of ASD in sighted children *do not* distinguish children with ASD and significant vision loss from children without ASD and significant vision loss.

Researchers have given particular attention to young blind children who exhibit autistic-like behaviors. The recent study of Williams et al. (2014) included parent reports based on a modified version of the Autism Diagnostic Interview, Revised (ADI-R; Rutter et al. 2003). Several parents of young blind children noted significant differences in their children's autistic-like symptoms before and after the age of 5 years. They reported that as their children developed and became comfortable exploring their environments, their social and communicative behaviors increased greatly, while their repetitive behaviors decreased proportionally. Similarly, a much earlier study of congenitally blind children found that various stereotypic behaviors occur during the first and second years of life, but many decrease from the age of 3 years onward (Troster et al. 1991). The findings also appear consistent with research by Hobson and Lee (2010), who reassessed nine congenitally blind children and seven sighted comparison children, all of whom had met diagnostic criteria for ASD, 8 years earlier. The results of reassessment determined that only one of the blind children met criteria for ASD, although all seven sighted children continued to meet the criteria. Thus, the message to clinicians is to use caution in diagnosing ASD in very young children with vision impairment, as the symptoms experienced by some children may improve significantly as they develop further (Williams et al. 2014).

Differentiating between autistic-like behaviors related to blindness and those essential to a diagnosis of ASD is particularly challenging, especially if clinicians have limited experience with blind children. When considering children with significant vision loss, there is risk of misinterpreting the basis of a child's behaviors if the

child is not provided appropriate modes and opportunities to develop and demonstrate competence.

Future Directions

Clearly, efforts must be directed toward the development of screening and assessment tools for identification of ASD in individuals with significant vision loss. Current diagnostic screening and assessment tools are heavily weighted with visually based features and tasks, having been designed for use with sighted children. The components of tools for use with individuals who have significant visual loss need to be grounded in modalities other than solely visual. Researchers and clinician will need to devise alternative equivalents for criteria that are basic to current measures, such as eye contact, directed gaze, and joint attention. The development of such measures is in very preliminary stages. A key concern is the lack of information regarding the progression of social development in the very heterogeneous population of individuals with significant vision loss. Much is yet to be learned. Normative data on social development in children with visual impairment are necessary to best inform diagnostic criteria for ASD in this population.

Directly tied to identification of ASD in children who are blind or who have significant visual impairment is the need for appropriate teaching methods, tools, and strategies for this population. It has not been established whether the current instructional interventions used with sighted children who have ASD are the most appropriate for children with significant vision loss, nor whether the various means can be adapted to be such. The question merits investigation, with the ultimate goal of developing strategies, tools, and materials to address the specific learning needs of this population.

Through the review of studies regarding blindness and ASD, it is readily apparent that efforts have been focused nearly exclusively on children, especially young children. A near void exists regarding information about ASD in blind adults. A broader, life course perspective is called for in future studies.

Block Design Subtest

Timothy Soto and Cate Kraper

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Block design is a subtest that is administered as part of several of the Wechsler Intelligence tests, including the Wechsler Preschool and Primary Scale of Intelligence (WPPSI, the Wechsler Intelligence Scale for Children-fourth edition (WISC-IV; Wechsler 2003) and the Wechsler Adult Intelligence Scale-fourth edition (WAIS-IV; Wechsler 2008). This subtest is included in the calculation of Performance IQ. It is primarily a measure of visual-spatial and organizational processing abilities, as well as nonverbal problem-solving skills. Because it is a timed task, it is also influenced by fine motor skills. The individual is presented with identical blocks with surfaces of solid red, surfaces of solid white, and surfaces that are half red and half white. Using an increasing number of these blocks, the individual is required to replicate a pattern that the test administrator presents to them – first as a physical model, and then as a two-dimensional picture. The number of blocks required to match the presented models increases and the patterns become increasingly difficult to visually dissect into components.

Individuals who do well on this subtest tend to have an aptitude for perceiving spatial patterns and for flexible problem solving; performance is also aided by the ability to work quickly. Conversely, one factor that may hinder an individual's performance on block design is the presence of high anxiety or perfectionistic tendencies (Hopko et al. 2005), as these can lead to an overly cautious approach that causes the individual to finish after the time limit. Poor performance may also be related to a number of factors that affect an individual's ability to perceive spatial patterns, manipulate objects, or integrate visual and spatial information. Of note, individuals

Blitz-Nick-Salaam Krämpfe

► Infantile Spasms/West Syndrome

with autism spectrum disorders have been observed to show superior performance on the block design task (Shah and Frith 1993). This relative strength is described by the hypothesis of the Weak Central Coherence Theory, which suggests individuals with autism have difficulty seeing the “big picture,” and instead may perceive parts of the whole with more relative skill than individuals without autism (Happé and Frith 2006).

While not captured in the final score of block design, it is clinically useful to observe how an individual approaches this task. One such behavior that can be informative to the test administrator includes the above-mentioned perfectionistic tendency, or alternatively, the tendency to be impulsive or careless. An individual's persistence may also be noted, as well as whether the individual tends to approach the pattern in a piecemeal fashion, or in a more global fashion.

Medicine, New Haven, CT, USA

Synonyms

[Blood-oxygen-level dependence](#)

Definition

Blood-oxygen-level-dependent (BOLD) signal is the magnetic resonance imaging (MRI) contrast of blood deoxyhemoglobin. Seiji Ogawa and his colleagues first discovered this intrinsic contrast mechanism in 1990. Neurons do not store internal reserves of glucose and oxygen, which are essential to their proper function. Increases in neuronal activity, typically in response to a demand for information processing, require more glucose and oxygen to be rapidly delivered via the blood stream. Via this hemodynamic response, blood releases glucose and oxygen to active neurons at a faster rate relative to inactive neurons. This results in a surplus of oxyhemoglobin localized

to the active area, giving rise to a measureable change in the local ratio of oxy- to deoxyhemoglobin, thus providing a localizable marker of activity for MRI.

Board Certified Associate Behavior Analyst

Mary Jane Weiss and Samantha Russo
Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Synonyms

[BCaBA](#); [BCBA](#); [BCBA-D](#)

Definition

The Behavior Analyst Certification Board[®], Inc. (BACB[®]) credentials practitioners at four levels. The different categories denote varied depths of training and levels of independence in practice.

Individuals who apply to become *Board Certified Behavior Analysts*[®] (BCBA[®]) must possess at least a master's degree, have 225 classroom hours of specific graduate-level coursework, meet supervised experience requirements, and pass the BCBA examination. In order to use the *Board Certified Behavior Analyst - Doctoral (BCBA-D)* designation, a BCBA must possess an acceptable doctoral degree and meet other criteria. As of 2015, applicants for the BCBA credential will need to have completed 270 h of specific coursework.

Persons who apply to become *Board Certified Assistant Behavior Analysts*[®] (BCaBA[®]) must have at least a bachelor's degree, have 135 classroom hours of specific coursework, meet supervised experience requirements, and pass the BCaBA examination. The BCaBA must have 1000 h of supervised independent field or 670 practicum hours or 500 intensive practicum hours. Once certified, BCaBAs must be supervised by a BCBA; this supervision requirement includes supervision for 5% of hours for the first 1000 h post certification and then ongoing supervision for at least 2% of hours following the initial 1000 post certification hours.

A recently added credential, *Registered Behavior Technician*, has created a professional level for behavior technicians. Individuals with this credential must practice under a BCBA, BCaBA, or FL-CBA. In order to obtain the RBT credential, the individual must have a high school diploma, complete 40 h of training, pass a competency exam, and demonstrate competency across a task list.

Experience and training requirements at all levels of certification are rigorous and ensure that certificants meet minimal competence levels in their knowledge and abilities. BACB certificants must accumulate continuing education credit and recertify over 3 years to maintain their credential. In addition, certificants must annually confirm that they remain in compliance with the

BACB's standards, including ethical guidelines and disciplinary standards.

Because certification requirements periodically change as standards are increased, readers are encouraged to consult (www.bacb.com) for updated information.

Body Movements, Imitation of

Giacomo Vivanti

A.J. Drexel Autism Institute, Drexel University,
Philadelphia, PA, USA

Synonyms

[Gestural imitation](#); [Imitation of intransitive actions](#); [Imitation of nonmeaningful gestures](#)

Definition

Imitation of body movements involves copying acts that do not include the use of objects, do not lead to an end state, do not carry a specific meaning, and can only be described in terms of changes of limb postures in space (e.g., a hand moving across a forehead). Current models of imitation suggest that imitation of body movements is supported by mechanisms that partially differ from those underlying the imitation of actions that carry a semantic meaning (e.g., opening a container or waving goodbye). While imitation of body movement is supported by a “direct visuo-spatial route” in which the visual input is directly mapped into a motor output, imitation of actions that carry a semantic meaning is achieved via a “semantic route” in which previous knowledge on the meaning of the action can be recruited (Tessari and Rumiati 2004). Given that the familiarity with the demonstrator's goals and means cannot be exploited in this type of imitative task, imitation of body movement is considered to provide a rigorous methodology by which to assess “true imitation” in human and comparative research.

Early signs of the ability to imitate body movements are reported to be present since early

infancy, and mutual imitation games between child and caregiver, involving affective mirroring and copying of body movements, are observed throughout infancy and toddlerhood across cultures. These early reciprocal exchanges are thought to promote social bonding and to provide a foundation for social cognitive development (Meltzoff 2002; Stern 1985).

Difficulties in imitating body movements in individuals with autism are reported in many studies that used different stimuli, coding systems, and comparison groups (including different clinical populations) and across a wide range of IQ, language levels, and chronological ages (see Edwards 2014; Rogers and Williams 2006). Differences in the way individuals with autism imitate body movements include (1) reduced frequency of spontaneous imitation and (2) diminished accuracy of imitative performance. While autism-specific deficits are documented in several imitative tasks, imitation of body movements appears to be more impaired than imitation of actions carrying a semantic meaning in this population (Vivanti and Hamilton 2014; Williams et al. 2004). Various explanations have been hypothesized to account for these difficulties in autism, including abnormalities in visual attention, a primary deficit in the perception-action mapping implemented by the mirror neuron system, a reduced motivation to imitate, and a primary deficit in motor execution. However, none of this explanation is supported by unequivocal evidence. Since children with autism have difficulties in many of the neurocognitive processes involved in imitation of body movements, including visual attention to the demonstration, social motivation, motor planning, and executive processes, it is likely that a heterogeneous vulnerability in the components of the imitative process, rather than a single cause, affects the ability to imitate body movements in individuals with autism.

IQ scores below average but above an intellectual disability (ID). People with BIF may have adaptive functioning deficits similar to those experienced by people with mild intellectual disabilities (ID) but are often denied critical services that are available to people with ID diagnoses because their IQs scores are too high (Peltopuro et al. 2014).

Adults with borderline intellectual functioning, with or without autism, often require supports similar to those beneficial to people with mild ID. Comprehensive case management is a valuable and effective method of supporting adults with borderline intellectual functioning. Comprehensive case management involves a primary support professional or team of professionals working collaboratively to help individuals set, pursue, and attain goals for health, safety, employment, socialization, and independence. Case management often begins with addressing concrete or urgent needs, such as for housing, healthcare, or employment, and expands to promote social-emotional wellbeing and personal fulfilment. It involves coordination of care across many service systems and domains and is highly individualized.

Borderline Intellectual Functioning and Comprehensive Case Management

Cara G. Streit
Threshold Program, Lesley University,
Cambridge, MA, USA

Definition

Borderline intellectual functioning (BIF) is a little-known and little-utilized classification that has historically described individuals who have

Historical Background

The history of borderline intellectual functioning as an official diagnosis is one of progressively declining prominence and usefulness (Wieland and Zitman 2016). In the DSM-II, what is referred to here as borderline intellectual functioning was called borderline mental retardation. In the DSM-III, borderline mental retardation (i.e., BIF) was removed from mental retardation and reclassified as a V code, leaving a whole population of individuals without a suitable diagnosis. It remained a V code in the DSM-IV-TR and was defined using an IQ score range of 71–84. In the DSM-5, the IQ range was removed, leaving it with little definition and limited usefulness as a classification.

The DSM-5 leaves gray area in the diagnosis of intellectual disability as well, by emphasizing a person's adaptive functioning and the diagnosing clinician's judgement over score in making the diagnosis. In practice, this means that some

children and adults whose IQ scores are over 70 (who may have previously been described as having BIF) may now receive ID diagnoses, while others may not. This gray area is particularly concerning considering the difficulty of accurately measuring IQ in people with autism (Rao et al. 2015).

The IQ score range of 71–84 is between 1 and 2 standard deviations below the mean of the standardized distribution of scores. Because the scores fit a normal curve, as much as 13.6% of people fall into this IQ range. The incidence of BIF is nearly twice as high among people with autism. According to the Centers for Disease Control’s 2012 prevalence data, 24.5% of children with autism have IQ scores in the range of 71–84, compared with 31.6% in the range of an intellectual disability and 43.9% with average or above average IQ (Christensen et al. 2016). While they may have a diagnosis of autism without intellectual disability, according to the DSM-5, this system of classification does not capture their borderline intellectual functioning unless it is specifically noted with a V code by the diagnosing clinician. Children with BIF are known to be at increased risk for persistent mental health issues (Jankowska 2016), poor social functioning drug abuse (Gigi et al. 2014), poor parenting, and school adjustment issues (Jankowska et al. 2014), making it critically important that BIF be recognized.

Rationale or Underlying Theory

While some children and adults with borderline intellectual functioning may have only mild adaptive functioning deficits, or even none at all, others experience deficits comparable to those experienced by individuals with mild intellectual disabilities. A review of the literature on BIF shows that, compared with peers who have average IQ scores, people with BIF have lower performance on tests of cognitive and academic skills, hold jobs that are lower-skilled and lower-paid, have poorer executive functioning and abstract reasoning, have slower processing speeds, and are more likely to be incarcerated or

charged with crimes, have mental health problems, or display antisocial behaviors (Peltopuro et al. 2014). On many of these measures, people with BIF fall between people with specific learning disabilities and those with mild intellectual disabilities. Authors of the review conclude that people with BIF may be in a “worse situation” than adults with MID (mild intellectual disability) or with SLDs (specific learning disabilities) (p. 438). They explain that “because the problems with BIF are not as visible as those in MID and not as specific as those in SLDs, they often go unrecognized and, consequently, no support is offered.” In the United States, a diagnosis of an ID is required to receive certain critical supports, services, and government entitlements; people with BIF are denied services that could dramatically improve their life circumstances, all because of their slightly higher IQ scores. Children and adults with a diagnosis of autism who have IQ scores in this range may be able to qualify for some supports and services based on their autism diagnosis, even without an accompanying diagnosis of ID. However, this is not the case in all places or for all services.

In the United States, children with disabilities are guaranteed a free and appropriate public education. A child who fits the, albeit vague, classification for borderline intellectual functioning (but not intellectual disability) may have another diagnosis, like autism, a specific learning disability, or ADHD, that can qualify them for public school services and accommodations. As an adult, these diagnoses do not guarantee comprehensive state or federal services.

Shattuck et al. (2012) note that while research on services and interventions for children with autism has become more robust in sync with the increasing prevalence of autism diagnoses, research on adult services has been slow to follow. It is clear that autism can be impactful across the lifespan and that adults with autism have unmet service needs in multiple life domains (Turcotte et al. 2016). This is particularly true for individuals with BIF or ID, and appropriate services are less available to adults with BIF than to adults with ID. The services that do exist tend to be siloed; for example, an adult with autism and

BIF can access employment supports from their state vocational rehabilitation agency but may need another agency to provide assistance in managing an apartment in order to live independently. Adult service systems are generally not designed to work seamlessly together to support the needs of each individual accessing them, and an adult with BIF may not even qualify for services from all the individual systems that would be relevant for their goals. Those they do qualify for can be difficult for someone with a cognitive impairment to access and utilize effectively. Filling out paperwork, getting to appointments on time, and finding an unfamiliar service location can all be significant challenges for someone with borderline intellectual functioning. Case managers can assist people with BIF find and use the services they need and coordinate care across services.

For adults with intellectual disabilities, case management may be provided by a state developmental disability agency and/or the staff of a residential program and it may or may not be comprehensive. For adults who do not live in staffed residences and who do not qualify for services from a state developmental disability agency due to relatively higher IQ scores, as is the case for most adults with borderline intellectual functioning, comprehensive case management must come from another source. Adults with autism and borderline intellectual functioning, or their families and supporters, should check with their state developmental disability agency to find out whether they qualify for case management from the state even with IQ scores higher than those required for a diagnosis of an intellectual disability. If not, this type of case management may be offered privately by individuals or by disability service organizations, either for profit or not for profit.

Goals and Objectives

The goal of comprehensive case management is to support adults in setting, pursuing, attaining, and maintaining goals of their own choosing and to

promote their overall health, safety, happiness, and well-being. Typically, comprehensive case management is most useful when an individual has multiple or complex goals, or has struggled with setting or attaining goals in the past. It may also be particularly useful for people with a dual diagnosis or a special health care need. Goals may include:

- Finding employment
- Living independently
- Making friends and learning how to manage relationships
- Managing adult responsibilities, like keeping up an apartment and organizing important paperwork
- Learning how to navigate public transportation
- Improved budgeting and money management
- Securing and/or managing entitlements and benefits (health insurance, Social Security payments, affordable housing, etc.)
- Attaining a higher level of education
- Coordinating health care services
- Planning for life after the death of parents or caretakers
- Any other goal that could be supported by a case manager

Goals should be set by the client, with the support of the case manager and of other people who are involved in life-planning with the client (e.g., family members, mental health clinicians, doctors, and educators).

Treatment Participants

Ideal candidates for comprehensive case management are adults with borderline intellectual functioning who require support in one or more areas in order to achieve the level of independence, community participation, and social engagement they desire. Adults with a range of adaptive functioning skills can benefit from case management, and the more significant the person's adaptive functioning deficits, the more intensive and comprehensive the case

management needs to be. Adults of any age can benefit from comprehensive case management and ideal services will follow an individual through their lifespan.

Clients of comprehensive case management may have a range of diagnoses in addition to their below average IQ scores. They may have autism, cerebral palsy, a brain injury, special health care needs, or genetic disorders, to name a few. Conversely, they may have no official diagnosis, but a history of educational and adaptive functioning deficits with no known etiology, other than an IQ score in the borderline range.

Treatment Procedures

While this section is titled “Treatment Procedures” for consistency within the publication, comprehensive case management should not be considered treatment. Rather, it is a system of support and communication that comes together underneath an individual in order to help them rise up to their potential. The professional coordinating an individual’s case management must foster a culture of collaboration with the individual, their family members, and their other providers that supports their self-determination, bolsters their independence, and encourages them to make their own choices.

Comprehensive case management might entail weekly meetings with a client, or may be more or less frequent depending on what the client wants and needs. Some clients may only need relatively short-term intervention, for example, help finding new health insurance when they can no longer be on a family member’s, or may need long-term services if their goals are more complicated. A client with complex goals, fewer state, federal, and nonprofit supports, less family support, or multiple diagnoses may need long-term case management that helps them manage issues and pursue goals in multiple domains and settings throughout their lives. Services should always be highly individualized in their frequency, duration, and in the level of hands-on assistance provided by the case manager.

Organizations offering comprehensive case management should be prepared to follow clients throughout their lives; this reduces the number of transitions for the individual, helps with building provider/client rapport, and streamlines long-term planning efforts and the preparation for later life. Within organizations, providers who are leaving should take care to transition clients thoughtfully to new case managers.

Services must be fully accessible to each individual client. Some common accommodations include:

- Emailing or calling the client to remind them of appointments
- Communicating by the client’s preferred method (email, phone, text, instant messaging, etc.)
- Providing physically accessible meeting spaces
- Travel training to help the client learn how to get to and from the case manager’s office or service location
- Communicating directly with family members, with the client’s permission
- Converting any documents the client needs into accessible formats

Case managers should refer their clients out for specialized services beyond their expertise or licensure, such as psychotherapy and medical care, but should coordinate the connection between the client and the specialist to whatever degree the client requires; this may mean setting up a first appointment together, showing the individual how to get to the specialist, or even traveling to a first appointment with the client if necessary and desired by the individual. Of course, the case manager must receive permission from the client when communicating with any other parties about their case management or other coordinated services. As much as possible, clients should be guided in advocating for themselves with family members and providers, and case managers should avoid speaking for them except when clients request it and when it is

absolutely necessary for clear communication. Instead, case managers can help clients develop scripts for communicating their needs to others, make phone calls together on speaker phone, and attend meetings together, if such support is necessary.

Efficacy Information

There is no body of literature specifically on the efficacy of comprehensive case management in improving outcomes for adults with BIF. However, data from the Lesley University Threshold Program, which serves young adults with BIF, suggests that 2 years of case management in the context of a college-based postsecondary program may contribute to positive employment, social, and independent living outcomes (Lesley University 2015). Graduates of the Threshold program have a paid employment rate of 79% and work an average of 31 hours per week. Threshold program alumni may choose to continue participating in comprehensive case management throughout their lives, provided by the program.

The efficacy of comprehensive case management varies depending on the experience, persistence, and flexibility of the case manager, the motivation of the client, the complexity of the goals being pursued, and the level of other supports available to the client. A highly efficacious case manager will ensure that communication with the client is through a method comfortable and convenient to the client, will be quickly responsive to the client, and will reach out to the client if there is any concern that they need additional supports in order to effectively utilize the case management.

Outcome Measurement

Individual outcomes should be measured by setting goals for case management, directed by the client, and checking-in on those goals together at predetermined times or as necessary. For many clients, comprehensive case management can be

deintensified or even phased out over time as the client develops the skills to manage a wider range of responsibilities on their own.

Qualifications of Treatment Providers

Providers will typically have a background in human services, social work, mental health counselling, special education, vocational rehabilitation, or a related field. Providers need broad knowledge of the educational and adult service systems available to people with disabilities. Depending on the organization through which case management is offered, additional licensure or education may be required.

Definition

Brain connectivity refers to both structural connections between distinct regions of the brain as well as coordinated functional activity within networks of different brain regions, which may or may not share direct structural connections. Structural and functional connectivity in the brain are interrelated in that altered structural connections can affect functional coordination within brain networks and altered functional activity can affect structural connections via adaptive changes from synaptic pruning and dendritic arborization. Although there is extensive evidence to support altered structural connectivity in the brain in individuals with autism (for a specific example, see ► [“Corpus Callosum Abnormalities in Autism”](#)), most brain connectivity theories of autism spectrum disorder (ASD) focus on differences in functional connectivity (FC), defined as “temporal correlations between spatially remote neurophysiological events” (Friston et al. 1993). In this regard, FC is most often measured by comparing correlations between brain regions for fluctuations of the blood oxygen-level-dependent (BOLD) response from fMRI data (see Functional Magnetic Resonance Imaging) that is collected during passive rest (no stimulus) or during the completion of a cognitive processing task. Accumulating

evidence from this line of research suggests that the development of typical FC patterns in the brain are altered in individuals with ASD. For instance, early investigations reported general patterns of global hypoconnectivity (under-connectivity) in individuals with ASD (Just et al. 2004), but subsequent studies have indicated more complex patterns of both hypo- and hyper-connectivity across different brain regions and networks. As such, general patterns of global (long-range) hypoconnectivity coupled with local (short-range) hyperconnectivity have also been proposed (Wass 2011). However, these theories oversimplify much more complex alterations of brain connectivity in individuals with ASD, especially regarding the development of FC over time. Models of optimized brain organization exhibit robust FC between neighboring brain regions with some additional long-range connections to more distant regions in order to minimize the metabolic cost of information processing. Consistent with this model, maturational changes of brain networks typically involve functional segregation between non-contributing anatomical neighbors with concurrent integration of more distant brain regions that contribute to the processing of domain-specific information (Fair et al. 2009). Conceptualized within this developmental framework, emerging theories of brain connectivity in ASD suggest that information processing is affected by disruption of the maturation and adaptive development of functional integration within as well as segregation between brain networks (Rudie et al. 2013).

More recent research into disruptions of brain connectivity in ASD have reported some promising results, but the well-known heterogeneity in the etiology, neurobiology, and symptomatology of ASD across individuals suggests that there is most likely not a unique or defining brain connectivity pattern. It is also not yet clear whether FC differences contribute directly to the pathogenesis of the disorder or only emerge as secondary features associated with altered cognitive and behavioral performance. Overall, brain connectivity appears to be altered in individuals with ASD with patterns of both under-connectivity and

over-connectivity depending on the brain region or network that is being evaluated (Abbott et al. 2016). Such alterations may reduce functional network integration to affect cognitive and behavioral processing in some of the core and comorbid domains. However, the substantial variability in reports of FC alterations across individuals coupled with methodological concerns regarding fMRI data processing (Müller et al. 2011) presents major considerations and limitations for previous FC studies in ASD. Brain connectivity will need to be evaluated in larger samples with sufficient power to subgroup individuals with ASD. These subgroups should be compared to individuals with other neuropsychiatric disorders as well as typically developing controls in order to determine whether any ASD-specific alterations in brain connectivity actually exist and elucidate their potential relationship with differences in the pathogenesis of the disorder.

Definition

Brainstem audiometry, sometimes called a brainstem auditory evoked response (BAER) or an auditory brainstem response (ABR), is an electrophysiologic test that assesses the auditory system through the low brainstem. This test can assess hearing sensitivity in individuals who cannot respond to traditional testing; thus, it is often used in newborn hearing screenings and in populations that are nonverbal. The ABR is completed by placing recording electrodes on the individual's head and ears and placing earphones in their ears. Responses are elicited using click and tonal stimuli which are delivered through the earphones. Five waveforms are typically present in the ABR (waves I, II, III, IV, and V); however, wave V is the waveform used for threshold testing. Individuals with autism spectrum disorders might not be able to consistently respond to

Definition

Brainstem Auditory Evoked Potentials (BAEP) are low-amplitude electrical voltage potentials in the brain that are evoked by a sound, often a click, and recorded using electrodes on the scalp (i.e., electroencephalography or EEG). Since the potentials typically have an amplitude around 1 mV, hundreds of trials are averaged together to provide data with adequate signal to noise ratio. BAEPs have been used as a tool to examine brainstem integrity and hearing ability clinically since the 1970s, helping to diagnose tumors and other diseases such as multiple sclerosis. BAEPs are particularly useful with patients who are difficult to test by traditional audiometry, where feedback is required, because of compromised levels of consciousness, limited communication, or behavioral noncompliance. BAEPs are also useful for detecting subtle changes that may be clinically relevant, and localizing the deficits.

The BAEP reflects the function of the auditory nerve (eighth nerve), cochlear nucleus, superior olive, and inferior colliculus, measuring the time it takes an aural stimulus to travel through the auditory pathway in the brainstem. They are thought to measure action potentials and postsynaptic activity propagating along the auditory nerve, and to other regions along the auditory pathway. When measured in response to a brief stimulus (typically a click) in the ear canal via an inserted earphone or headphone, the elicited waveform response is detected by surface electrodes placed at the base of the scalp and the ear lobes. The BAEP generally includes seven waves, but it is the initial five waves that have been the most extensively studied and are useful for clinical applications. These five waves occur within 6 or 7 ms and are labeled waves I through V. Abnormalities in specific waves are informative, as they are thought to localize the differences to particular parts of the auditory pathway. Wave I is believed to reflect the distal auditory nerve on the ipsilateral side; wave II, proximal auditory nerve on the ipsilateral side; wave III, ipsilateral cochlear nucleus; wave IV, superior olivary nucleus and adjacent brainstem regions bilaterally; and wave V, distal lateral lemniscus and inferior colliculus on the contralateral

side. Interpretation of the BAEP is routinely done by examining the latency and length of these waves and the interpeak intervals between them (IPI), also known as interpeak latencies (IPL). The amplitudes are less frequently interpreted because they are more variable across individuals, and thought to be less reliable indices of dysfunction. The IPIs are considered particularly important, reflecting the conduction times in the auditory pathway through the brainstem (i.e., auditory nerve then cochlear nerve, cochlear nucleus, and lateral lemniscus). Therefore, longer IPIs are thought to indicate impaired function, possibly related to the number, synchronicity, or integrity of the neurons firing in these regions.

The BAEP is relatively adult-like by 18 months of age, though wave V may continue to mature until 3 or 4 years of age. They differ in females and males, with a slightly shorter latency and higher amplitude in females. More recently, the BAEP has been examined in response to a tone (instead of a click), which is thought to measure dysfunction more specific to the cochlear regions.

Definition

BAERs (brainstem auditory evoked responses; also referred to as brainstem auditory evoked potential, BAEPs, and auditory brainstem response, ABR) measure the electrical voltage potentials in the proximal auditory pathway in response to a noise. This is done via electrodes on the scalp and earlobe (see also definition: ► “Brainstem Auditory Evoked Potentials”). The noise is most frequently a click, but tones and other sounds have also been used (e.g., Russo et al. 2008). BAERs are thought to reflect the function of the auditory pathway through the brainstem, providing insight into both the level of hearing and the integrity of brainstem function in a given individual. When the noise is a click, BAEPs produce seven waves of activity. The first five of these – labeled waves I through V – have been well characterized, with wave V followed by a negative dip (Stone et al. 2009). These initial five waves occur within about 7 ms. The waves are thought to reflect activation progressing as the

aural stimulus moves from more distal regions of the auditory nerve to the more proximal regions. Examining the length of the waves and the latencies between them (the interpeak intervals: IPIs, also known as interpeak latencies IPL) provides insight into whether there is dysfunction along the auditory pathway through the brainstem and, potentially, helps to localize that dysfunction. Waves I, III, and V have been particularly well characterized. Wave I is thought to be generated peripherally, at the auditory or cochlear nerve; wave III at the cochlear nuclei; and wave V at the lateral lemniscus. These signals go from the ipsilateral side (waves I to III in the auditory nerve, cochlear nucleus, and superior olive) to bilateral brainstem regions (wave IV) to contralateral regions (wave V in the lateral lemniscus and inferior colliculus). The wave structure develops an adult-like architecture in the first few years of life, with maturation starting in more peripheral regions (with waves I and III maturing in the first year) and moving to more central regions (with wave V maturing at 3–4 years of age; Fujikawa-Brooks et al. 2010; Moore and Linthicum 2007).

Historical Background

Since sensory modulation is disrupted in ASD, with both under- and over-reactivity to sounds, early theories posited that auditory brainstem function might be affected in ASD (Ornitz et al. 1985; modified in Ornitz 1987). To empirically study this possibility, BAERs were used, examining the integrity of this region and the claim of atypical brainstem function in ASD. Early work on autism in the 1970s and early 1980s was promising, suggesting that there may be abnormalities in BAERs in individuals with ASD. A problem, however, was that what aspect of BAERs actually differed in ASD was not consistent across studies (Klin 1993). In addition, BAERs do not require attention or consciousness, making them useful for testing special populations; however, this fact also led to a very heterogeneous sample being tested in many of these early studies. Some of the participants had known neurological conditions (Klin 1993; Minshew 1991), and in some

studies, many individuals had hearing loss (e.g., Taylor et al. 1982), which create an obvious confound when interpreting these studies. Gender has been shown to affect BAERs, with shorter latencies in women. Therefore, gender also has to be considered since a greater proportion of women in the control group could lead to spurious group differences. Indeed, the conclusion that BAERs were abnormal in ASD was disputed in the mid-1980s by work suggesting that the differences reported in the early studies reflected participant characteristics other than ASD (e.g., other neurological disorder, intellectual disability). Courchesne et al. (1985) tested a cohort of high-functioning individuals with ASD, with well-matched controls, and found no differences in the group with ASD. Once the issues discussed above were taken into account – and the reliability of the measures, as methods were still improving – several reviews argued that differences in individuals with ASD were not evident (Minshew 1991) or less likely (Klin 1993). Klin (1993) pointed out that, while BAERS did not provide convincing evidence of brainstem dysfunction in ASD, they did suggest that peripheral hearing loss might be common in ASD and such hearing loss would be important clinically when treating those with ASD. Tables listing the results and the samples used in these earlier studies are included in Klin (1993) and Wong and Wong (1991).

Current Knowledge

More work has led to further inconsistencies in the data, though several important themes have emerged. In all studies, differences in the BAERs of those with ASD are evident in a subset of participants with ASD and, in some cases, their first-degree relatives (Maziade et al. 2000). This indicates that, while abnormal BAERs are not causal, they may reflect a subgroup which would be important to identify clinically (Nagy and Loveland 2002). Thus, there is still potential for abnormal BAERs to be a biomarker for at least a subset of individuals with ASD, providing insight into the disorder. In addition, what is atypical in the BAERs of the individuals with ASD has

differed both within and across studies, suggesting that there may be multiple ways to disrupt the auditory pathway through the brainstem. These disruptions generally present as prolongations of the waves or IPIs, when they are evident. Nagy and colleagues argue that some of these disruptions may be specific to ASD (e.g., prolongation of waves III to V; on the basis of Bachevalier 1996), while others might be evident in a number of disorders (e.g., speech impairment, ADHD: prolongation of waves I to III) and are potentially related to differences in language acquisition (Nagy and Loveland 2002). In general, it is not clear whether even the differences that have been identified in ASD are specific to this disorder. However, these differences do not generalize to *all* developmental disorders. While individuals with Down's syndrome also display abnormal BAERS, the atypical patterns are distinct from those in autism (Sersen et al. 1990). Finally, abnormalities may have implications clinically, as recent work suggests that there may be some experience-dependent plasticity in the BAER wave pattern that is sensitive to auditory training (Chandrasekaran and Kraus 2010; Skoe and Kraus 2010; see Russo et al. 2010 for training in ASD).

The studies in recent years have shown a prolongation of either the wave itself or – relatedly – the IPI (Gillberg et al. 1983; Kwon et al. 2007; Maziade et al. 2000; Rosenhall et al. 2003; Tanguay et al. 1982; Tas et al. 2007; Wong and Wong 1991), though a few early studies indicated a shortening of waves (see Table 1 in Rosenhall et al. 2003 for a summary of earlier studies). Other conditions, such as Down's syndrome, may tend to exhibit shorter IPIs (Sersen et al. 1990). This longer latency is evident in a subset of those with ASD, generally not more than about 50% of the sample. Which wave (I, III, or V) or IPI the group differences are evident differs between studies; however, wave V appears to be most often affected, especially in the left (L) ear. (See Table 1 for a summary of recent results since 2000 to click tones in BAERs.) This may reflect a more general slowing of auditory processing that differs across this heterogeneous population. This pattern is also evident in many earlier studies.

Brainstem Auditory Evoked Responses in Autism (BAERs), Table 1 Recent literature on BAERs in ASD in response to clicks (see Russo et al. 2008; Tharpe et al.

2006 for recent evidence of differences in BAERs to other sounds, but not to clicks)

Study	N	Potential confounds?	Prolongation?	Prolongation? IPIs I–III, III–V
			Latencies I, III, V	
Tas et al. (2007)	N = 30 ASD N = 15 controls M age = 3 year	Individuals with ASD sedated controls not	None	III–V
Rosenhall et al. (2003)	N = 101 ASD with normal hearing N = 59 controls M age = 8 year	Controls slightly older than individuals with ASD	I, V	III–V
Fujikawa-Brooks et al. (2010)	N = 20 ASD N = 20 controls M age = 10 year		V in L ear	None
Maziade et al. (2000)	N = 73 ASD, 251 relatives N = 521 controls M age = 7 year		Not reported	Longer I–III and I–V in ASD and first-degree relatives especially siblings
Magliaro et al. (2010)	N = 16 ASD N = 25 controls M age = 12 year	Many more F in control group (16 vs. 1)	III, V	I–III, I–V
Kwon et al. (2007)	N = 71 ASD (22 autism) N = 50 controls M age = 3 year	May have had other medical issues, 2 cases with brainstem abnormalities	V in L ear	I–V, III–V bilateral in larger more heterogeneous ASD group only

B

Skoff and colleagues reported prolonged III–V IPIs in the L ear in 33% of their sample (1980). Thivierge et al. found that 80% of their populations had longer I–V and III–V IPIs (1990). Wong and Wong (1991) reported increased latencies of wave V, and I–III, III–V, and I–V IPIs, in sedated individuals with autistic “features,” but not in those with intellectual disability. Later studies (summarized in Table 1) reported longer IPIs I–III in both individuals

with ASD and their first-degree family members (Maziade et al. 2000). However, 52% of the families with ASD had normal BAEPs in everyone in the family. Rosenhall et al. (2003) reported that 58% of children with ASD had longer latencies in waves I and V and IPI in III–V. This study included a large sample, but a portion of the sample had hearing loss. Kwon et al. (2007) reported longer I–V and III–V and wave V in large group of those on the spectrum (ASD)

($N = 71$), but not in those with autism defined more strictly ($N = 22$). The take-home message from Kwon and colleagues was that ASD might have a lot of physiological overlap with central auditory processing disorder (CAPD), on the basis of the ABR results, and that this comorbidity might have clinical implications. In contrast to these positive results, several studies have reported no difference between groups to click stimuli (Courchesne et al. 1985; Rumsey 1984; Tharpe et al. 2006).

Most of the studies do not have a well-matched control group (but see Courchesne et al. 1985), although many of the recent ones do a test for hearing impairment before including participants in the results. In addition, since BAERs are thought to be relatively resistant to age, function level, or other potential confounds such as the effects of sedation, these differences may generally not affect the results or do so only subtly. However, in these studies, there are still issues with the control groups. One such issue is gender. Since females have shorter IPIs, including too many in the control group could bias the IPIs to be shorter in controls and therefore appear longer in ASD. For instance, Magliaro et al. (2010) found prolongation in III and V and IPIs I–III and I–V, but this study included a substantial proportion of females in the control group. Recent studies have attempted to control for gender (Russo et al. 2008), since there are almost always a few more females in the control group, and have found differences. Another issue is that a number of subjects with serious hearing loss *and* ASD have been identified across studies (Rosenhall et al. 2003; Tas et al. 2007). This is an important issue clinically, as it may not be immediately evident in children with ASD that they have hearing loss (Klin 1993). So, while this emphasizes the importance of examining hearing in those with ASD, it also presents confounds in the available data. For instance, Tas (2007) reported a longer III–V bilaterally in young children with ASD. However, five children were identified as having hearing loss, and, while the three with severe loss were excluded, the two with mild hearing loss were not. This study also brings up the issue of using quite

young children, around 2 years old (see also Kwon et al. 2007; Wong and Wong 1991). While the BAER architecture is relatively mature by 18 months of age, there is some evidence that wave V continues to mature until around 3 or 4 years old. While age was approximately matched in many of the studies, differential development across groups may still be influencing the results.

Several studies have examined the BAER response to sounds other than clicks, and these results suggest that group differences might be more likely with sounds other than with the traditional click response. Russo et al. (2008) examined pitch encoding. They found that 20% of children on the autism spectrum had difficulty with pitch, while none showed abnormal BAERs to click sounds, but this result was not correlated with language outcome. The ASD group had more boys and lower IQ, but the results did not change when these issues were controlled statistically. Tharpe et al. (2006) found differences in the BAER when the stimulus was a pure tone, but not when it was a click. This difference was evident in 11 of 22 individuals with ASD. Fujiwaka-Brooks and colleagues (2010) included more clicks per second (61–91 instead of 11–25 used typically), a stressor that is known to lead to longer latencies typically, especially in wave V. These investigators found differences in left ear only, with a trend for latency of wave I and significant results of wave V. They also report a negative correlation between the latency of wave V and verbal IQ, suggesting a relationship between this wave and language skill. About half the sample showed the difference in the L ear for wave V. This group points out the importance of testing from both ears, as some studies have only tested the right ear.

Future Directions

These studies indicate that BAERs *may* be abnormal in ASD, but this is unlikely to reflect important information about etiology across the spectrum. These abnormal BAERs may reflect disrupted auditory processing, possibly deep in

the brainstem. There is not convincing evidence that it is specific to ASD. However, that differences are evident for only a subset of participants with ASD might prove useful for identifying subgroups of ASD. In addition, differences in the developmental pattern in ASD have not been studied but may be enlightening. While TD individuals may show little change in the BAERs after age 4 or due to intellectual disability, this pattern may not be true of those with ASD. Such developmental differences could help explain the discrepancy between the findings of Courchesne et al. (1985) with a high-functioning set of adults with ASD and well-matched controls and the more recent work that generally focuses on children, often very young ones (Kwon et al. 2007; Tas et al. 2007; Wong and Wong 1991). In addition, recent studies have begun to identify plasticity in the BAER in the auditory pathway in the brainstem when training takes place (Chandrasekaran and Kraus 2010; Skoe and Kraus 2010; see Russo et al. 2010 for studies in ASD), and high-functioning individuals with ASD may be able to compensate for their social and communication issues and engage further through language. This plasticity may help to explain the variability in the BAER differences in ASD, in addition to other differences across the spectrum, as well as help to inform potential interventions.

Brainstem Evoked Response (BER)

► Evoked Potentials

Brazil and Autism

Helena Brentani, Guilherme Vanoni Polanczyk and Euripedes Constantino Miguel

Department of Psychiatry, Faculty of Medicine, University of Sao Paulo, Sao Paulo, Brazil

Services and Social Policies

In Brazil, Autism Spectrum Disorder (ASD) is considerably understudied. A single epidemiological study has been conducted, assessing children from one city in the southeast. Results indicated an estimated prevalence of 27.2/10,000, which is believed to be an underestimation due to methodological issues (Paula et al. 2011). If the international prevalence 1% is true in Brazil, approximately 1.5–2 million Brazilian children are affected by ASD.

The National Health System (SUS), still in constant construction, also has shortcomings. Although a national system, it is organized in different ways around the country. The SUS recommends that children with autism have comprehensive care of their needs. Health care occurs primarily in units of ambulatory medical care (AMAS) and psychosocial care centers (CAPS). The Brazilian health system is composed by the primary care for simple demands (Basic Health Units – UBS, Health Nuclei for Family Support – NASF, and Family Health Units – USF), secondary care (CAPS – Outpatient Mental Health) for more difficult cases without need of hospitalization, and tertiary care for hospitalizations and emergency room needs (General Hospitals). It is sure that this network needs to be improved: the CAPS only recently started to assist children with autism in a more regular way. There are some welfare agency in Brazil that plays an important role in the diligence of autism patients and families, such as ABRA – Associação Brasileira de Autismo brings together corporations related to autism in Brazil and represents the interests of Autism patients in different national councils such as the health, social, and the rights of the

individual council; AMA – Associação de Amigos do Autista; and the APAE – Associação de Pais e Amigos dos Excepcionais, and they have an established center in most Brazilian states. They offer different activities for autism patients related to socialization, day care activities, and communication; AUMA – Associação dos Amigos da Criança Autista – since 1990 has the major objective of developing educational programs of social adaptation for autism patients and families.

In São Paulo, the richest state in the country, the health system is designed in a way that the Basic Health Units (UBS), teams of the Family Health Strategy (family physicians, nurses, and dentists), with support from the Family Assistance Center (NASF) are the first place where cases arrive to make diagnosis and also less-severity cases are kept for treatment. The instruments for early identification and diagnosis should be present in established practice in these centers, which unfortunately does not happen. The CAPS is responsible for the establishment of a therapeutic project and is the reference for the UBS (secondary care, in day hospital care scheme, more intensive, with intermediate function between the outpatient and inpatient) and when faced with cases of high complexity, CAPS can trigger other places in the network, as services belonging to the university or references to specific service for ASD. São Paulo is the unique state that has a specific CAPS for adults with autism.

Regarding education, children with autism should be included in regular education (inclusive education), which should provide suitable conditions for integration and development. Teachers and school staff should receive adequate training to work with children with autism. In cases that regular education is not possible given the intensity of symptoms and difficulty of the student to adapt, the option is a special school. Getting a place in special school is very difficult, and parents often have to appeal to justice to have their rights guaranteed. In Brazil, people with autism have all the rights provided for in specific laws for people with disabilities as well as international standards signed by Brazil, such as United Nation Convention on the Rights of

Persons with Disabilities. Moreover, children and adolescents also have all the rights stated in the Statute of Children and Adolescents and the elderly, i.e., over 60 years old, have also the rights of the elderly. People with autism have also the special protection of Federal Law, which ensures proper treatment in public and private health facilities for the specific pathology they have. If the person with autism is demonstrably in need, he/she is entitled to a free pass in state and interstate transportation. The law, establishing the National Policy on Protection of Rights for Persons with Autism Spectrum Disorder, was published in the Official Newspaper in Brazil in December 2012 giving support and emphasis on rights and proper treatment, as well as access to education and to vocational teaching, housing, labor market, and social security and welfare. In cases of proven need, the person with autism spectrum disorder, included in common classes in regular education, will be entitled to have a specialized companion during the activities done in the school. Among the points set out in the Law is community participation in the formulation of public policies for people with autism, in addition to implementation, monitoring, and evaluation of the person with autism. In addition to these duties, the benefit of greater importance to the disabled person and therefore to person with autism is the Continuous Cash Benefit, a social assistance benefit which was regulated by the Organic Law of Social Assistance – LOAS. To get the benefit, the family income must be less than one fourth of the minimum wage, and proof of disability and level of temporary or permanent disability for independent life and work must be attested by medical and social expertise of the INSS. In the next section, we will explore diagnosis and treatment options for autism with an emphasis on research performed in Brazil and the Brazilian limitations.

Instruments for Diagnosis and Standard Scales in Brazil

The official diagnosis of ASD in Brazil follows the ICD-10 criteria (WHO 1993), performed by

Brazil and Autism, Table 1 Translated and validated instruments for screening and diagnosis of Autism Spectrum Disorders

Description of instruments		
<i>The Autistic Traits of Evaluation Scale (ATA)</i>	Authors	Ballabriga et al. 1994
	Proposal	Scale of screening based on observation
	Age of administration	Over 2 years
	Reliability	Favors tracking the evolution of the disease
	Validation for Brazil	Assumpção et al. 1999
<i>Autism Behavior Checklist (ABC)</i>	Authors	Krug et al. 1980
	Proposal	Direct observation and interview with parents and caregivers for screening
	Age of administration	Over 18 months
	Reliability	Identifies autism in both clinical and educational contexts
	Validation for Brazil	Marteletto and Pedromônico 2005
<i>Childhood Autism Rating Scale (CARS)</i>	Authors	Schopler et al. 1986
	Proposal	Assessment scale for observation of behavior for screening
	Age of administration	Over 24 months
	Reliability	High degree of internal consistency and reliability
	Validation for Brazil	Pereira and Wagner 2008
<i>Autism Screening Questionnaire (ASQ)</i>	Authors	Berument et al. 1999
	Proposal	Self-administration questionnaire for parents and caregivers for screening
	Age of administration	Over 6 years
	Reliability	Favors the large-scale use for screening of suspected cases of autism
	Validation for Brazil	Sato et al. 2009
<i>Autism Diagnostic Interview (ADI-R)</i>	Authors	Lord et al. 1994
	Proposal	Semi-structured interviews with parents or guardians for diagnosis and research on autism
	Age of administration	Over 18 months
	Reliability	Validated and reliable instrument for diagnosis of (GDD** TGD) for ASD in preschool aged
	Validation for Brazil	Becker et al. 2012

interviews held with parents and caregivers and by clinical observation of the child. To assist in the diagnostic process, several scales and interviews were validated to Portuguese. Table 1 shows the translated and validated scales and instruments for use in Brazil: The ATA (Escala d'Avaluació dels Trests Autistes), ABC (Autism Behavior Checklist), M-CHAT (Modified Checklist for Autism in

Toddlers), and the ASQ (Autism Screening Questionnaire) are used for screening, while the CARS (Childhood Autism Rating Scale) and ADI-R (Autism Diagnostic Interview-reviewed) are used for diagnosis.

The ATA (Autistic Traits of Evaluation Scale) was the first scale to be translated and adapted in Brazil by Assumpção Jr. et al. The translation of

the ABC made by Marteleto and Pedromônico in 2005 added the direct observation of the child as well as interviews with parents and caregivers. The M-CHAT (Modified scale for screening autism) was translated and adapted to Portuguese in Brazil by Mirella Fiuza Losapio and Milena Pereira Pondé 2008 creating the possibility of early screening, which could be done in public health at the primary care level. The questionnaire for children older than 6 years has been translated and validated in Brazil by Sato et al. in 2009. But, in Brazil there is still no study comparing the use of these scales in our social reality, and it would be important to establish protocols for screening.

The CARS is a scale that helps identify children with autism and it distinguishes from children with developmental impairment and without autism. Its importance is to differentiate mild-moderate autism from severe the CARS has two versions. One observational and one held with parents or guardians. The scale for parents was translated and validated in 2007 in Brazil (Riesgo and Wagner 2008). The ADI has been translated into 11 languages, and it is cited as the gold standard for diagnosis of autism. In Brazil, the translation and validation of the ADI-R (Becker et al. 2012) has recently been published.

It is important to note the CARS alone does not indicate diagnosis (Riesgo and Wagner 2008), it must be used together with the DSM IV diagnostic criteria for autism. Santos et al. (2012) concluded that the CARS fails in the diagnosis of some cases of autism, while the ABC may result in *overdiagnosis*, and it is best to combine the use of both. Corroborating studies show that instruments used in isolation may not be sufficient, and it is important to use at least one questionnaire with parents and an observation scale with the kid. The administration of the ADI-R is complex and lengthy requiring trained professionals to such situations that are nonexistent in our society, even the little time availability of the ADI-R for use in Brazil.

In an attempt to use instruments already validated and translated and applied in Brazilian clinical practice, Duarte et al. (2003) examined the validity of the CBCL/4-18 (Child Behavior

Checklist) for the identification of autism spectrum disorders in the Brazilian population. The CBCL was validated for the administration to the Brazilian population by Bordin et al. (1995). As Albores-Gallo et al. (2008) pointed out, the CBCL is an important instrument to assess the most frequent comorbidities in autism spectrum disorders, such as attention problems, depression, and anxiety, and not automatically valid for diagnosis.

Some Brazilian researchers have been working in the development of national scales for fast and easy administration for early detection of autistic symptoms (children younger than 18 months). The Clinical Indicators of Risk for Child Development (IRDI) was developed in Brazil, and it has the ability to detect a trend of occurrence of problems expressed in the first 18 months of life that extends throughout the development of the child at least until the sixth year, generating impact on the quality of life of the child (Kupfer et al. 2010). They are currently working on the validation of the IRDI for large-scale administration in Brazil, in partnership with the Brazilian government. Braido (2006) reported different behaviors and properties of behaviors (e.g., response latency) that already showed signs of delay in the development of babies (1 year old) who were lately diagnosed with autism. Following this line of research to identify behaviors, Bagaiolo et al. (2010) used the description of the child development from 0 to 3 years in order to analyze home videos of a baby who was lately diagnosed with autism (diagnosed with 3 years of age). Different failures in aspects of child development, before 3 years of age, were analyzed for association with autism risk. This work is still in progress requiring replication.

Regarded as the gold standard for diagnosis, the *Autism Diagnostic Observation Scale* – ADOS (Lord et al. 1994, 2000), ADOS-G has been already translated (personal communication by Maria Clara Pacifico, Cristiane S de Paula, and Guiomar Oliveira 2012) but has not yet been published or validated. The limitation of trained human resources for its administration also prevents the use of the ADOS-G in clinical practice.

Neuropsychological and Speech Pathology Evaluation

In Brazil, several instruments are used for neuropsychological and speech pathology assessment, and there is no standardized protocol. The use of Wechsler Intelligence Scale for Children-III, Wechsler Adult Intelligence Scale-III, and ADAPTATIVE BEHAVIOR SCALES OF VINELAND are recommended for assessment for autism in Brazil. From the standpoint of speech pathology, adapted scales and instruments to the Brazilian society are ABFW tests – Child language test in the areas of phonology, vocabulary, fluency, and pragmatics (Andrade et al. 2004); PPVT– Peabody Picture Vocabulary Test (Capovilla and Capovilla 1997); Language Exam (Braz and Pellicciotti 1988); the Evaluation of Symbolic Maturity (Befi-Lopes et al. 2000); and the language development evaluation (Menezes 2004).

Genetic Evaluation in Brazilian Clinical Practice

In terms of familial and genetic studies conducted in Brazil, we emphasized the study by Mecca et al. (2011) that aimed to track the occurrence of signs and symptoms of ASD in siblings of individuals with this diagnosis. The data indicate higher rates than those reported in the literature (2–6 %) and approach the findings that report 10 % of familial recurrence in dizygotic twins. This result provides evidences of possible neurogenetic factors to explain the occurrence of ASD in relatives of studied probands and emphasizes the need to make the tracking of this disorder in children who are not only evaluated but also their brothers. Brazil is beginning to contribute to genetic studies in the field of ASD and has adequate technology to conduct them. In the last 5 years (2008–2013), more than 11 genetic studies in patients with ASD were made in Brazil, most of which were case studies and some association studies, and case–control or family studies (simplex or multiplex) (Kuczynski et al. 2009; Griesi-Oliveira et al. 2012; Mulatinho et al. 2012;

Baruffi et al. 2012; Griesi-Oliveira et al. 2012; Christofolini et al. 2012; Longo et al. 2009; Castro et al. 2010; Orabona et al. 2009; Campos Junior et al. 2011). Although the Brazilian researches have made some contributions in the genetics of ASD, there is no panel for gene diagnosis in the Brazilian population yet, and the genetic evaluation is not part of the systematic evaluations in private clinics or public ones.

Overview of Current Treatments and Research Related to Treatment Strategies

In Brazil, it is recommended to follow the interventions followed by ABA (Applied Behavior Analysis), TEACCH (Treatment and Education of Autistic and related Communication handicapped Children), and PECS (Picture Exchange Communication System) in order to maximize language acquisition and improve communication skills. All the *AMA – Associação de Amigos do Autista* – in most of Brazilian regions offer different activities mainly based on TEACCH and PECS. Due to the high cost of professional training and the difficulty of administering such interventions in Brazil, it is needed that the research related to modifications of these therapies being either in time, performance in groups, or frequency. Below we present examples of work groups of Brazilian researchers studying single pre-evaluations for appropriateness of inclusion of children at different levels of PECS, time of administration of it as well as the speech pathology therapies in individual or in pairs.

The PECS is a simple and portable equipment, especially produced to ensure that communication with autistic children occurs in spite of their speech difficulties, but previous studies (Flippin et al. 2010) reported that many failures in the *PECS* training may be due to the fact that the child has not acquired all conditional discrimination training required. So before you start training the *PECS*, it is important to assess whether the individual already has such discrimination. In 2003, Guilhardi compared the performance of participants in *ABLA (Assessment of Basic*

Learning Abilities) and conditional discrimination training and equivalence testing. The author aimed to investigate whether the ABLA test results could predict the performance of children with typical development and atypical development (autism, cerebral palsy, congenital syndromes, etc.) in tasks involving the same type of stimulus. Guilhardi (2003) concluded that the predictive power of the ABLA for training equivalence does not happen to all participants and also there were no differences in predictive ability between types of conditional discrimination tests. In Brazil, Godoi et al. (2008) made a study of two cases to investigate the effectiveness of PECS in terms of assessing the amount of training necessary to acquire the skills involved in functional communication exchanging pictures. The authors measured also some side effects of PECS training, i.e., the interference of training on the frequency and appropriate verbalizations and about learning other behaviors specific to each participant. Parallel to the PECS training, additional training for other behaviors was done. These additional training involved differential reinforcement and *fading out* physical tips. As a side effect of this training, Godoi et al. (2008) pointed out the increasing frequency of verbalizations of both groups of participants. Furthermore, according to the authors, the structured and concrete features of the training contributed to the increased frequency of specific behaviors of each participant and independence in an everyday activity. Aiming to understand even more specifically the effects of picture exchange communication on language acquisition, Guilhardi (2009) investigated the functional independence of tacts and mands between verbal responses based on selection of stimuli (PECS). According to the author, the results showed functional independence between operant tacts and mands with verbal responses based on the selection of stimuli.

Cardoso and Fernandes (2006) and Fernandes et al. (2008) did studies with children and adolescents with psychiatric diagnosis within the autistic spectrum at the beginning of the process of speech pathology therapy and they were divided into three groups (individual language

therapy, child in a group with a coordinator, child in a group without a coordinator) according to the therapeutic intervention received for a period of 6 months; the results indicated no statistically significant differences between the groups; however, the group with most progress during the specific period of differentiated intervention was the one where the individuals were treated with a coordinator. The most interesting was that in none of the groups decrease in the levels of improvement obtained after a period of 6 months was observed, and in some situations, the number of individuals with improvement increased after this period. The results of this study reinforce the adequacy of procedures for determining the individual profile of abilities and disabilities of each individual as a basis for definitions regarding to the adopted intervention model.

In terms of pharmacological treatments, not all medications are available in the SUS and there are restrictive conditions according to diagnosis. For example, the majority of atypical antipsychotics are only offered to individuals with the diagnosis of schizophrenia. Besides, we do not have proper clinical trials performed in our country to examine the use of medications in autism. Despite methodological limitations, the study of Novaes et al. (2008) concluded that pharmacological interventions with second-generation antipsychotics seemed useful for the control of behavioral disorders such as psychomotor agitation and aggressive behavior in a sample of Brazilian patients with autistic spectrum disorders corroborating worldwide studies in the area.

Priorities and Future Directions

A systematic review of the Brazilian scientific literature on ASD showed a significant increase in scientific production in this subject over the last 2 years (Teixeira et al. 2010). On the other hand, it showed that most publications are not focused on subjects that can contribute significantly to the improvement of public health relating to autism in Brazil. Most publications make references to intervention studies without controls and small

convenience samples, and the use of validated diagnostic and neuropsychosocial instruments are still required.

Another intriguing finding is the extreme concentration of scientific production in only two regions of the country. Researchers from São Paulo and Rio Grande do Sul are the first authors in 90 % of papers published between 2002 and 2009 (Teixeira et al. 2010). In a recent editorial, De Paula et al. 2011 list the barriers and difficulties as well as the priority areas for investment in autism in Brazil. Some identified challenges include lack of specific funding to support autism research, lack of national multicenter projects, lack of trained researchers and clinicians in various disciplines, lack of robust scientific studies, and lack of campaigns to increase knowledge and understanding by the general public and professionals in education and health. The priorities identified for response to the challenges encountered are by (De Paula et al. 2011).

1. Research areas – to build capacity of research in various disciplines through programs of research training and training of clinicians, including diagnostic skills and tools for early detection and interventions
2. Awareness – to raise public understanding and improve public perception of autism by making information more accessible to the public
3. Services – to build capacity for services in Brazil among professionals and in community-based settings, to establish training program for screening early detection and intervention strategies

All these activities are very important to improve the understanding and assistance of autism in Brazil.

Description

The Behavior Rating Inventory of Executive Function (BRIEF) is a questionnaire that assesses executive functioning behaviors of school-aged children, ages 5–18 (Gioia et al. 2000). Executive functioning is the ability to actively engage in an assortment of interrelated processes that are responsible for guiding goal-directed cognitive, emotional, and behavioral functioning. Both parent and teacher rating forms of the BRIEF exist, providing opportunities to rate executive functioning across home and school settings. The BRIEF is appropriate for the assessment of children with a variety of developmental, neurological, psychiatric, and medical conditions. It has also been normed and applied in samples of children with autism spectrum disorder (ASD).

The BRIEF consists of 86 items that cluster into eight clinical scales reflecting different aspects of executive functioning. The scales are entitled: Inhibit, Shift, Emotional Control, Initiate, Working Memory, Plan/Organize, Organization of Materials, and Monitor. Three of these scales combine to create the Behavioral Regulation Index (BRI), and five comprise the Metacognition Index (MI). All eight clinical scales of the BRIEF combine to yield the Global Executive Composite (GEC).

The BRI reflects the ability to shift cognitive set and to modulate behavior and emotion by exerting appropriate inhibitory control. The BRI is comprised of the Inhibit, Shift, and Emotional Control scales. The Inhibit scale assesses the ability to resist acting on an impulse or refrain from engaging in an impulsive behavior as appropriate to the situation. The Shift scale measures the ability to respond to changing circumstantial demands by flexibly transitioning from one activity, situation, or aspect of a problem to another. The Emotional Control scale quantifies the ability to regulate emotions and display emotional reactions that are situationally and developmentally appropriate.

The MI reflects the ability to cognitively manage tasks by effectively initiating, planning, organizing, and monitoring goal-oriented behaviors.

The MI is comprised of the Initiate, Working Memory, Plan/Organize, Organization of Materials, and Monitor scales. The Initiate scale measures the ability to independently begin a task or activity, including generating ideas or problem-solving strategies. The Working Memory scale assesses the ability to hold information in mind and to mentally manipulate information for the purpose of completing a task. The capacity to effectively sustain performance and attention is also integral to items on this scale. The Plan/Organize scale evaluates the ability to apply order to information, anticipate future events, set goals, and develop appropriate, often sequential, steps in the service of task completion. The Organization of Materials scale quantifies the child's ability to organize his or her work and play activities, as well as environment (e.g., possessions, storage, and work spaces). The Monitor scale assesses the ability to continuously engage in work-checking behaviors in order to ensure attainment of the designated goal. The scale also measures the child's ability to continuously evaluate how his or her behavior affects others.

In addition to the primary clinical scales, the questionnaire yields two validity scales, assessing inconsistency and negativity of the reporter. The Inconsistency scale of the BRIEF consists of ten pairs of items that are strongly correlated with one another. This scale is included in order to measure rater consistency. The Negativity scale is comprised of the nine items that were least frequently rated as "often" in the normative sample. High Negativity scale scores can indicate an excessively negative perception on the part of the rater, though at times they are also seen in profiles of children with very high levels of executive dysfunction.

The BRIEF is intended to be completed in a single sitting, requiring approximately 10–15 minutes. Each scale and summary index yields a T score, which have a mean of 50 and a standard deviation of 10. Scores above 65 are considered clinically elevated. Percentile scores are also provided. While the BRIEF can be administered by individuals who do not possess formal training, interpretation of scores requires relevant graduate training in the field of psychology.

Historical Background

The BRIEF was developed by neuropsychologists Gerard Gioia, PhD, Peter Isquith, PhD, Steven Guy, PhD, and Lauren Kenworthy, PhD, and published in 2000 by Psychological Assessment Resources, Inc. It was designed to measure children's executive functioning in real-world settings, as observed by parents, teachers, and caregivers. BRIEF items were generated from clinical interviews conducted by the authors, based on common concerns elicited from parents and teachers. The initial draft of the questionnaire included 129 items for the parent form and 127 items for the teacher form. The set of items was determined to match a fourth- to fifth-grade reading level, as intended by the authors.

Following initial item development, twelve neuropsychologists reviewed and categorized all items into their appropriate executive functioning domains. Principal factor analysis was then conducted to further clarify clustering of items. In the final version of the BRIEF, over 80 % of items retained had at least 75 % agreement among authors and expert raters regarding how well they fell within their designated scales.

Within the BRIEF, moderate to high correlations were found between most scales. Therefore, in order to strengthen the validity of the BRIEF scale structure, factor analysis was conducted, using normative and clinical samples for both the parent and teacher forms. Based on the results of a principal factor analysis, a two-factor structure was identified. This two-factor solution accounted for 74 % of the variance in parent forms and 83 % of the variance in teacher forms. The two factors derived from this analysis, entitled the Behavior Regulation Index (BRI) and Metacognition Index (MI), subsequently have been used to capture all eight scales of the BRIEF.

The BRIEF represents the first informant report measure of executive functioning available for use with children and adolescents. Strengths include the ability to measure multiple domains of executive functioning simultaneously. This feature can be contrasted with research and clinical task-based assessments,

which often quantify isolated abilities in distinct executive domains. By utilizing caregiver report of daily functioning, the BRIEF also claims high ecological validity, as findings reflect, and are generalizable to, executive functioning capacity in various real-life settings (Kenworthy et al. 2008). Criticisms of the BRIEF concern the validity and potential for bias inherent in any informant report measure. In addition, concerns have been raised about whether executive functions can truly be parsed into individual domains, as is suggested by the eight BRIEF scales. It has been noted that such parsing of the broader executive functioning construct is not yet well grounded in neuroimaging research regarding brain function (Denckla 2002).

Psychometric Data

The BRIEF was standardized and validated in a sample of school-aged children from diverse racial, socioeconomic, and geographic backgrounds. The normative sample included 1,419 parent forms and 720 teacher forms, for children between 5 and 18 years of age, attending public and private schools in Maryland. Approximately half of the normative sample was male, and no children had a history of special education or psychiatric medication. Among parent responders, 83 % were mothers.

From the normative raw data, T scores and percentile norms were developed for each of the eight BRIEF scales, the BRI and MI, and the GEC. T scores were generated using a linear transformation of raw scores. Percentiles were assigned based on the distribution of raw scores for each scale, index, and GEC. As for other behavior rating scales, BRIEF scales are positively skewed, so that the majority of cases cluster at the lower, normal end of each scale, while scores in the tail represent deviations from the norm.

Several aspects of test reliability were assessed using data from the normative sample. Internal consistency quantifies the degree to which items within individual scales are consistent with each

other and is statistically evaluated using Cronbach's alpha coefficient. Psychometric data indicated that across all individual scales and composite indices, in both parent and teacher forms, Cronbach's alpha values ranged from 0.80 to 0.98. These values indicate good to excellent internal reliability within scales.

Inter-rater reliability was also measured to determine consensus across parent and teacher forms completed for a subset of 296 children within the normative sample. Inter-rater reliability was found to range from 0.15 to 0.50 across the different scales and composites. These values indicate low reliability across raters; however, the authors note that low inter-rater reliability is expected given that these forms are intended to capture any existing variability in children's behavior across different environmental settings. Inter-rater reliability was lowest for the Initiate and Organization of Materials scales; in general, parents tended to endorse more problematic functioning than did teachers.

Finally, test-retest reliability was assessed in order to measure how consistent individual raters were in reporting on a child's behavior at different but proximal time points. For the parent form, this data was computed from a subsample of 54 participants within the normative sample with an average interval of 2 weeks between questionnaire completions for a single rater. Test-retest reliability values ranged from 0.76 to 0.85 across individual scales and from 0.84 to 0.88 for the three composites, indicating good reliability. For the teacher form, test-retest reliability was computed in a subsample of 41 participants, over an average interval of 3.5 weeks. Test-retest reliability for the teacher form ranged from 0.83 to 0.92 for individual BRIEF scales and from 0.90 to 0.92 for the BRI, MI, and GEC. These values indicate good test-retest reliability for individual scales, and excellent reliability for the composites when rated twice by teachers.

In their manual, the BRIEF authors also address two aspects of test validity or the extent to which the BRIEF measures what it proposes to measure. Content validity, reflects the degree to

which the content of the test instrument itself (i.e., BRIEF items) adequately captures all aspects of the construct (i.e., executive functioning) it purports to measure. The fact that items were selected from clinical interviews and that there was strong agreement among pediatric neuropsychologists that items fit within their intended scales, serves to strengthen content validity for the BRIEF. In addition, during test development, scales were refined with item-total correlations (i.e., the extent to which an individual item correlated with the overall score for its scale). Inter-rater agreement among expert reviewers served as an external check for scale membership of each item.

Construct validity speaks to the degree to which the measure adequately captures the construct that it aims to address. It can be quantified by evaluating convergence with other measures that target the same construct, as well as divergence with measures targeting dissociable constructs. Evidence for good construct validity is found in high correlations between BRIEF scales and other pertinent measures, including the ADD-IV scale (Zhang et al. 2005), and several subscales of the Child Behavior Checklist (CBCL) (Achenbach 1991). Specifically, all scales were highly correlated with the ADD-IV summary scores, which is expected given that executive functioning problems are prominent in children with diagnosed attention and behavioral disorders. In addition, there is some evidence for specificity and dissociability of individual BRIEF scales with regard to the constructs they aim to capture. For example, the BRIEF Initiate scale correlated with the Withdrawn, Anxious/Depressed, and Attention Problems scales of the CBCL, whereas the BRIEF Working Memory scale correlated only with CBCL Attention Problems scale. The BRIEF Initiate scale correlated with both the CBCL Attention Problems and Aggressive Behavior scales, whereas the BRIEF Shift and Emotional Control scales correlated with the CBCL Aggressive Behavior scale alone. Evidence of divergence with constructs unrelated to executive functioning is evident in low correlation rates

between BRIEF scales and the CBCL Somatization scale. Convergent and divergent construct validity was also evaluated by comparing the BRIEF, the Behavior Assessment System for Children (BASC) (Reynolds 2004), and the ► [Conners' Parent Rating Scale](#).

Clinical Uses

Findings pertaining to the application of the BRIEF with children and adolescents diagnosed with ASD are available in the BRIEF manual. As part of measure development, the BRIEF was administered to parents ($n = 26$) and teachers ($n = 18$) of children with high-functioning ASD, as well as to parents ($n = 18$) and teachers ($n = 16$) of typically developing children with no psychiatric diagnoses. Relative to controls, scores for children with high-functioning ASD, including Autistic Disorder, Asperger's Disorder, and Pervasive Developmental Disorder – Not Otherwise Specified – were significantly elevated across all BRIEF scales and composite indices.

Similar to findings detailed in the BRIEF manual, primary research literature also confirms that the BRIEF is sensitive to differences between children with ASD and those with no psychiatric diagnoses. Thus, researchers have reported that when comparing BRIEF scores of high-functioning children with ASD to the standardization sample in the BRIEF manual, BRI, MI, and GEC composite scores were all clinically elevated on average (Gilotty et al. 2002; Kenworthy et al. 2005; Kenworthy et al. 2009; Winsler et al. 2007). More specifically, compared to BRIEF norms, approximately two-thirds of children with ASD scored in the clinically impaired range (i.e., T scores over 65) on the BRI, MI, and GEC (Kenworthy et al. 2005). There is also some evidence that when boys with ASD are compared to those with typical development, the pattern of generalized score elevations is most salient for the Shift scale (Mackinlay et al. 2006).

Research conducted within ASD samples has revealed a link between executive functioning

symptom elevations on the BRIEF and greater severity in core symptoms associated with the disorder. Namely, higher scores on the BRI were related to greater impairment in Communication, Reciprocal Social Interaction, and Restricted and Repetitive Behavior domains as assessed by the most widely used diagnostic measures for autism (i.e., Autism Diagnostic Observation Schedule, Autism Diagnostic Interview – Revised) (Kenworthy et al. 2009). Likewise higher BRI scores were associated with score elevations on a measure specifically targeting repetitive behaviors (Boyd et al. 2009). Increased MI scores, in contrast, were related to greater social symptom severity only (Kenworthy et al. 2009). However, when BRIEF scores were compared to scores on a measure of adaptive functioning, MI scores were significantly correlated with impairment in both the socialization and communication domains (Gilotty et al. 2002).

The clinical utility of the BRIEF for children with ASD has been examined in comparison to other clinical populations. Specifically, researchers have shown that individuals with ASD can be differentiated from others with psychiatric, learning, behavioral, and learning disorders based on their BRIEF profiles. For example, children with ASD have more elevated scores on the BRIEF than do those with reading disabilities or traumatic brain injury (Gioia et al. 2002). Some research has demonstrated similarities between the BRIEF profiles of children with ASD and those with attention-deficit/hyperactivity disorder (ADHD) (Gioia et al. 2002; Winsler et al. 2007). However, deficits in flexibility, as indexed by the Shift scale of the BRIEF, appear to be most characteristic of children with ASD (Gioia et al. 2002).

Taken together, research to date has demonstrated that the BRIEF is sensitive to behavioral impairments in regulatory and metacognitive functioning in children with ASD. The level of impairment and relation between BRIEF scores and adaptive functioning in this group underscore the importance of evaluating executive functioning when assessing and treating children with ASD. The BRIEF offers a unique tool for assessing this domain of behavior, as observed by adults

familiar with children's day-to-day functioning in real-world settings.

Brief Infant-Toddler Social and Emotional Assessment (BITSEA)

Ivy Giserman Kiss and Alice S. Carter
Department of Psychology, University of
Massachusetts Boston, Boston, MA, USA

Synonyms

BITSEA; BITSEA-ASD subscales

Description

The Brief Infant-Toddler Social and Emotional Assessment (BITSEA) (Briggs-Gowan and Carter 2006) is a 42-item caregiver-report broadband screening tool developed to identify social-emotional and behavior problems and delays in the acquisition of competencies in children 11–48-months of age. The BITSEA was derived from the longer (166 item) Infant-Toddler Social and Emotional Assessment (ITSEA; Carter and Briggs-Gowan 2000; Carter et al. 2003), which provides an in-depth analysis of emerging social-emotional development and intervention guidance. The BITSEA can be completed by caregiver report in approximately 5–7 minutes and is written at a fourth to sixth grade reading level (Briggs-Gowan et al. 2004). Items are rated on a three-point Likert scale, with the following anchors: not true/rarely (0), somewhat true/sometimes (1), and very true/often (2). The information gathered from the BITSEA covers a broad range of social-emotional and behavioral functioning and generates scores in internalizing, externalizing, and regulatory domains, as well as other areas that may be indicative of emerging psychopathology. Following the original scoring of the BITSEA, items are grouped into Problem and Competence domains that generate possible problem and possible delay/deviance cut-scores as well as percentiles based on national norms.

Of the total 42 items, the BITSEA contains 19 specific items that are consistent with early-

Brief Infant-Toddler Social and Emotional Assessment (BITSEA), Table 1 Behaviors assessed on BITSEA ASD subscales^a

Subscale	Psychometric properties	Behaviors assessed ^a
ASD-Problems	Sensitivity: 76% Specificity: 72% PPV: 68%	Limited enjoyment of playful activities
		Unresponsive when hurt
		Tactile sensitivities
		Difficulty with transitions
		Repetitive play
		Repetitive speech
		Repetitive motor movements
		Appears unaware of surroundings
		Limited eye contact
		Avoidant of physical contact
ASD-Competence	Sensitivity: 91% Specificity: 80% PPV: 77%	Shares successes
		Seeks out caregiver when upset
		Responds to name with eye contact
		Emotional/physical affection
		Interactive play
		Empathy when someone is hurt
		Imitation skills
		Use of pointing to share interests/joint attention
		Pretend play

^aAdapted from table originally published by Giserman Kiss et al. (2017)

emerging autism spectrum disorder (ASD) symptomatology (See Table 1). An important feature of the BITSEA is its inclusion of both positively and negatively worded items, relating to both problem behaviors and delayed competencies associated with ASD; thus the BITSEA ASD items make up two ASD-specific subscales: ASD-Problems and ASD-Competence. The ASD-Competence subscale consists of nine items that assess early social-emotional and social-communication competencies expected in typical development. The ASD-Problems subscale consists of ten individual items that assess social-communication impairments and repetitive and restricted behaviors commonly seen in young children with ASD. The ASD-Problems and ASD-Competence subscales are calculated and prorated if fewer than three items are missing from either scale. BITSEA ASD subscales can be scored individually or together, as an ASD-Total score; however, findings presented by Giserman Kiss et al. (2017) demonstrate that the ASD-Competence subscale is the most statistically and clinically effective of all three subscales

(see the Psychometric Data section for more information). Children with subscale scores exceeding ASD-Competence, ASD-Problem, or ASD-Total cutoffs are considered “at risk” for ASD, and further developmental assessment is strongly recommended.

The BITSEA allows clinicians to efficiently identify young children who are showing early symptoms of ASD, while simultaneously screening for early-emerging non-ASD social-emotional and behavior problems. Simultaneous screening may allow for more efficient assessments in fast-paced pediatric and early education settings and eliminate providers’ discomfort regarding introducing an ASD-specific screener to families who have not raised any concerns about their children’s social-emotional development, ultimately leading to increased universal screening.

Historical Background

The BITSEA was originally developed in response to the recognition of the importance of

early detection of and early intervention services for young children with social-emotional and behavioral deficits. While the ITSEA responded to this need and effectively identified children with early-emerging psychopathology, authors recognized the limitations of this tool, particularly regarding the time required for completion and scoring. With the recommendation for routine screening during well-child visits by the American Academy of Pediatrics (AAP 2001), as well as the introduction of managed care which resulted in shorter pediatric office visits, a more efficient questionnaire, the BITSEA, was derived from the pool of ITSEA questions. Original and replication studies of the full BITSEA demonstrated excellent test-retest reliability and good interrater agreement between parents when used in a socioeconomically and ethnically diverse community-based population (Briggs-Gowan et al. 2004; Kruzinga et al. 2012). Subsequent studies found strong prediction of concurrent psychiatric disorders (Briggs-Gowan et al. 2013) and good prediction to parent- and teacher-reported school-aged psychopathology (Briggs-Gowan and Carter 2008). In the original BITSEA manual, the authors recommended that the BITSEA be used for identifying young children with ASD, based on an at risk score on the overall competence scale as well as inspection of the scores for a subset of these ASD-consistent items. The ASD item pool was expanded to include sensory over- and under-responsivity following the publication of the DSM-5 criteria (APA 2013). However, cut-scores for the ASD items were not published.

The increased recognition of the benefits of early intervention services for children diagnosed with ASD (e.g., Pickles et al. 2016; Seida et al. 2009; Woods and Wetherby 2003), updated recommendations of the AAP and Centers for Disease Control for frequent developmental surveillance and screening (AAP 2006; Baio 2012), and common use of the BITSEA across research and clinical settings to identify toddlers at risk for ASD lead Giserman Kiss et al. (2017) to assess the feasibility of the BITSEA ASD subscales. The measure was tested in a sample that included young children with ASD, non-ASD

psychopathology, and typical development. Findings optimized cut-scores for each subscale that evidenced moderate to high discriminative power for detecting children with ASD. Of the three subscales, the ASD-Competence scale proved to be the most statistically and clinically effective (see the Psychometric Data section for more information).

Psychometric Data

Giserman Kiss et al. (2017) used receiver-operating characteristic (ROC) plots to determine optimal cut-scores on the BITSEA ASD subscales in a diverse sample of 512 young children (223 in the ASD group, and 289 in the non-ASD group) ranging in age from 15 to 48 months. Children in the non-ASD group included those with typical development as well as non-ASD early-emerging psychopathology. With regard to the ASD-Problems subscale, analyses using the optimized cut-score revealed moderate subscale accuracy (AUC = 0.81), 76% sensitivity, 72% specificity, and 68% positive predictive value (PPV). The ASD-Competence subscale optimized cut-score yielded stronger psychometric properties, as analyses evidenced high subscale accuracy (AUC = 0.92), 91% sensitivity, 80% specificity, and 77% PPV. Finally, the ASD-Total subscale optimized cut-score also yielded high subscale accuracy (AUC = 0.92), as well as 80% sensitivity, 79% specificity, and 77% PPV. Sensitivity and specificity rates for all three subscale optimized cut-scores in the subsample of children 24 months old and younger were comparable or stronger to rates in the overall sample. Importantly, the ASD-Competence subscale outperformed the other subscales in identifying both true positives and true negatives.

Post-hoc analyses explored the clinical characteristics of the children who screened positive despite not receiving an ASD diagnosis. Analyses revealed that children who screened as false positives on the ASD-Competence scale (i.e., screened positive but did not have ASD) had significantly lower nonverbal problem-

solving, receptive language, and expressive language abilities than children that screened as true negatives (i.e., screened negative and did not have ASD). In addition, children who screened as false negatives (i.e., screened negative but had ASD) had significantly higher receptive language scores than true positives (i.e., screened positive and had ASD).

Clinical Uses

It is recommended that the ASD-Competence subscale be used in pediatric primary care, early intervention, and early education settings to detect children at risk for ASD, while simultaneously assessing other areas of a child's development. The ASD-Competence subscale demonstrated strong psychometric properties and is quick and easy for providers to score. While the ASD-Total subscale also demonstrated high sensitivity, specificity, and PPV, scoring this subscale can be more cumbersome, error-prone, and time-consuming due to the additional items and need to perform calculations. Thus, providers are strongly encouraged to use the ASD-Competence subscale in order to examine a child's risk status for ASD, while simultaneously using the overall BITSEA to assess other social-emotional and behavioral domains, thus fulfilling the AAP and CDC's recommendations for regular developmental surveillance and screening. If a child's score on the ASD-Competence subscale exceeds the designated cut-score, caregivers should be counseled to seek further assessment of ASD symptoms, either through a second-stage observational screener, more in-depth conversation about the child's functioning across settings and relationships, or a developmental evaluation.

The broadband nature of the BITSEA may reduce the previously documented stress felt by caregivers during the ASD screening and diagnostic process (Siklos and Kerns 2007). A global screener that has a specific ASD subscale may give the provider additional time and avenues by which to introduce the idea of ASD. Moreover,

the use of positively as well as negatively worded questions on the BITSEA may be more acceptable to parents. Finally, given the increased risk for specific forms of psychopathology among children with ASD (e.g., anxiety, sleeping, and feeding disorders) (Ming et al. 2008), gathering information about symptoms beyond ASD may inform comprehensive intervention services, when needed.

Several limitations of the BITSEA ASD subscales should be kept in mind during use. Giserman Kiss et al. (2017) reported that the ASD-Competence subscale is possibly limited by its overlap with symptoms of general intellectual or developmental disabilities or other early-emerging psychopathology and also may be compromised by advanced language abilities. Thus, like any screening tool, the BITSEA should be used as an initial assessment and not as a diagnostic tool.

Brief Observation of Social Communication Change (BOSCC)

Rebecca Grzadzinski

Carolina Institute for Developmental Disabilities,
University of North Carolina, Chapel Hill,
NC, USA

Abbreviations

ADOS-2	Autism Diagnostic Observation Schedule, second Edition
ASD	Autism spectrum disorder
BOSCC	Brief Observation of Social Communication Change

Description

The Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al. 2016) is a treatment response measure of autism spectrum disorder (ASD) symptoms. The BOSCC is a behavioral coding scheme that is applied to 10–12 min videotaped social/play interactions between a child and a researcher or caregiver (play partner). The coding scheme was developed by expanding items from the Autism Diagnostic Observation Schedule, second Edition (ADOS-2; Lord et al. 2012), to quantify more nuanced variation in ASD symptoms. The BOSCC has been shown to be sensitive to changes in ASD symptoms from pre- to post-treatment (Divan et al. 2018; Frost et al. 2019; Gengoux et al. 2019; Grzadzinski et al. 2016; Kim et al. 2019; Kitzerow et al. 2015; Pijl et al. 2016), was designed to be flexible to use across sites/studies and coded by trained coders who were relatively naïve to ASD. As a measure of global ASD symptom change, studies show the BOSCC is most effective at quantifying treatment response in intervention trials examining improvements across a range of ASD symptoms. A module of the BOSCC for minimally verbal (those using single words or

less) toddlers or preschoolers is currently available to researchers with an applicable research study. Development of BOSCC modules for individuals with phrase to fluent speech are under development. Both the BOSCC play partner and coder can be unaware of the child's treatment status and time point, eliminating any potential bias associated with knowledge of the intervention.

Historical Background

Advances in developing efficacious interventions are limited by a lack of treatment response measures, without which researchers are hindered in evaluating intervention programs (French and Kennedy 2018). Many early interventions focus on improving core ASD symptoms (See ► [Need for Caregiver Support for Families of Children with ASD, The](#), and "Intervention During the Prodromal Stages of ASD"). Often subtle in nature, quantifying changes in core ASD symptoms is difficult (Anagnostou et al. 2015). Intervention programs have used the ADOS-2 to capture changes in ASD symptoms (Dawson et al. 2010; Estes et al. 2015) with limited success – perhaps since the ADOS-2 was developed to provide a diagnosis rather than measure changes in symptoms. There are additional limitations to using the ADOS-2 as well. Reliable use of the ADOS-2 requires substantial training and expertise of ASD, as well as substantial clinician and participant time (~45–60 min), limiting its use across sites and studies. As well as the ADOS-2, studies have used measures developed specifically for their intervention, impeding comparability across studies, or have focused on parent reports of improvement that, while important, may yield subjective information since parents are often aware of the child's treatment status (Bolte and Diehl 2013; Guastella et al. 2015). To address such limitations, the BOSCC was developed by expanding ADOS-2 items to increase sensitivity compared to a diagnostic coding scheme. The BOSCC administration is also shorter, and the coding can be completed by less experienced individuals who are unaware of the child's treatment status and time point.

Psychometric Data

The initial psychometric properties of the BOSCC were evaluated in a sample of 56 children participating in early intervention trials (Grzadzinski et al. 2016). Results of this and subsequent work indicate that the BOSCC has high inter-rater (intra-class correlation coefficients; ICCs = 0.88–0.98) and test-retest (ICCs = 0.79–0.90) reliabilities (Grzadzinski et al. 2016; Kim et al. 2019). These reliabilities have been further confirmed in independent samples (Frost et al. 2019; Kitzerow et al. 2015; Pijl et al. 2016). Results also showed statistically significant decreases (improvements) in BOSCC scores, with small to moderate effect sizes (effect sizes = 0.37–0.60), over 6 to 8 months of intervention (Grzadzinski et al. 2016; Kim et al. 2019). These improvements aligned with improvements observed in parent reports and standardized assessments of communication skills (Grzadzinski et al. 2016; Kim et al. 2019; Mullen 1995; Sparrow et al. 2005). Independent studies have also shown significant decreases in BOSCC scores over the course of intervention (Divan et al. 2018; Frost et al. 2019; Gengoux et al. 2019; Grzadzinski et al. 2016; Kim et al. 2019; Kitzerow et al. 2015; Pijl et al. 2016). However, not all intervention trials using the BOSCC have shown significant improvements. The amount of change observed may be dependent on characteristics of the intervention, such as intensity or duration (Fletcher-Watson et al. 2016; Nordahl-Hansen et al. 2016). See Grzadzinski and Lord, 2019 for a review of the BOSCC development.

Clinical Uses

The BOSCC is a treatment response measure that quantifies changes in ASD symptoms over the course of an intervention (See ► [Need for Caregiver Support for Families of Children with ASD, The](#), and "Intervention During the Prodromal Stages of ASD"). The BOSCC is not currently available for clinical use though can be obtained for use by researchers with an applicable

research study and who have completed appropriate training. The BOSCC is appropriate for minimally verbal (single words or less) toddler/preschoolers with ASD, and modules are currently under development for individuals with phrase to fluent speech. The BOSCC is not intended for use as an ASD screener (See “Screening for ASD and Developmental Delays in Infants and Toddlers”), diagnosis, or severity metric. The BOSCC’s ability to capture treatment response in other clinical conditions that may have overlapping symptoms with ASD (e.g., fragile X) remains an area of exploration.

³Institute of Health and Society, Sir James Spence Institute, Newcastle University, Royal Victoria Infirmary, Newcastle upon Tyne, UK

Definition

Autism spectrum disorder (ASD) twin and family studies showed during the 1990s that the behavioral phenotype extends beyond the clinical diagnoses of autism and ASD to include related milder behaviors or personality traits in the relatives of affected individuals. These qualitatively similar ASD-related behaviors in relatives are termed the broader autism phenotype (BAP) (see Losh et al. 2011, for a review). Although several authors have reported that these symptoms and traits are continuously distributed in the general population, the term “BAP” has not been used to describe individuals with social communication difficulties from population samples (see Constantino 2011, for a review of this literature).

Researchers have defined BAP characteristics using interview and questionnaire methods, neuropsychological and neurophysiological testing, and neuroimaging (Bailey and Parr 2003; Dawson et al. 2002; Losh et al. 2011). However, there is no formal definition of the BAP due to variability in approaches and research findings (see section “Historical Background”); indeed BAP is not a “diagnosis” recognized in the international diagnostic classification systems.

Thus, the best working definition of the BAP would be “individuals with the BAP show behavioral characteristics and personality traits similar to, but milder than, their relative with ASD” (see Current Knowledge).

Historical Background

Over the last 20 years, many groups have used a variety of instruments to define various characteristics in relatives of people with ASD. A large body of literature describes the different components of the BAP proposed following studies using a range of methodologies and measures in different populations (see Bailey et al. 1998, and Losh et al. 2011, for reviews). Research shows that in keeping with ASD, impaired social communication and social emotional abilities are core features of the BAP, together with repetitive behaviors (including obsessional behaviors) and behavioral rigidity (for reviews, see Parr et al. 2011 and Losh et al. 2011). Of all the BAP traits, repetitive behaviors, rigidity, perfectionism, obsessions, and circumscribed/special interests have been the most difficult to identify and quantify.

Two approaches have been taken to the investigation of these ASD-like behavioral traits. First, researchers have focused on identifying the BAP in families of one child with ASD (singleton families) and two or more people with ASD (multiplex families). Various groups have continued this research as part of the search for autism susceptibility genes (see the work of Piven, Dawson, and Parr et al. and the International Molecular Genetic Study of Autism Consortium [IMGSAC]). In addition to investigating the behavioral BAP within ASD families, researchers have focused on identifying neuropsychological components of the BAP in the relatives of people with ASD (Dawson et al. 2002). More recently, neurophysiological measurement and neuroimaging studies of relatives have been a focus (see Losh et al. 2011); the rationale for using all these approaches to BAP characterization is described by Bailey and Parr (2003). By contrast to this investigation of the relatives of people with ASD, other groups have conceptualized and measured a range of social communication and other difficulties in the context of normative trait variation in the general population hypothesizing that these traits could be included on a dimension with ASD (see Constantino 2011, for a review).

The BAP has been of increasing interest to researchers due to its potential importance for understanding the neurobiological nature of ASD (for a review, see Lainhart and Lange 2011). From 2000, research groups began collecting data from relatives in an attempt to assist in the search for ASD susceptibility genes, assuming that the BAP indexes a “genetic risk” that may be present in one or both parents and “unaffected” siblings – thus relatives might carry ASD susceptibility genes and express an “ASD-like” phenotype (see Bailey and Parr 2003, and Losh et al. 2011).

The most commonly used measures for the identification of BAP in affected families are summarized in Table 1. In keeping with ASD itself, reliable direct observation of BAP behaviors has been challenging. For this reason, most research groups have used some form of interview data, either exclusively or in combination with other measures. For most ASD molecular genetic studies, the BAP measures have been designed to dimensionalize the social communication difficulties of parents and children (e.g., quantitative trait loci studies) rather than to define an affected/unaffected categorical “cut-off score” – this means “the BAP” is less clearly defined than might be expected.

Current Knowledge

Research studies have shown that relatives of people with ASD have difficulties qualitatively

similar to those seen in ASD, but milder – the individual’s profile of difficulties does not meet clinical ASD threshold. Generally, males are more commonly and more severely affected than females, and relatives from multiplex families are more affected than those from singleton families. Children and young people may have difficulties with developing and maintaining friendships and problems relating to others. Children frequently have less well-developed social play than their same-age peers. Children and adults may be considered aloof. Language and communication difficulties are common. Perfectionism, obsessions, and rigidity may be seen. Considering mental health, the BAP has been associated with affective disorder (particularly depression). Whether depression is part of the BAP or is a function of having a relative with ASD remains unknown (for a detailed review, see Losh et al. 2011).

Investigation of the familial mechanisms that underpin ASD continue and, indeed, the finding that parents from multiplex and simplex ASD families show the BAP at different rates is likely to be important for our understanding of etiology. However, to date, the BAP has contributed only modestly to the understanding of the neurobiology of ASD or the identification of genetic variants (see Lainhart and Lange 2011 and Parr et al. 2011).

The impact of the BAP on the functioning of affected children, young people, and adults is similar to that seen in ASD itself, but milder, and usually results in less impairment in daily life.

Broader Autism Phenotype, Table 1 Broader autism phenotype measures

Instrument	Interview/ questionnaire/ observation	Populations used	References
Social responsiveness scale	Questionnaire	Twin, singleton, multiplex, and general pop samples	Constantino and Todd (2003)
BAPQ	Questionnaire	Singleton and multiplex families	Hurley et al. (2007)
BPASS	Interview and observation	Singleton and multiplex families	Dawson et al. (2007)
Family history interview and impression of interviewee	Interview and observation	Singleton and multiplex families	Parr et al. and the IMGSAC, in preparation

However, BAP traits may lead to difficulties with peer interactions and marital relationships and thus potentially difficulties at home, school, and in the workplace. People with BAP have varying degrees of insight into their difficulties and the impact of their behavior for themselves and others (Losh et al. 2011; Parr et al. 2011).

“BAP” is a term used in research and not usually in clinical practice. However, in clinical settings, with their knowledge of the importance of genetic factors in autism, relatives of people with ASD comment about their own ASD-related difficulties, or those of other family members. For clinicians, the challenge is how best to “classify” these difficulties shown by people who do not have ASD but who do experience some degree of social communication impairment. It is important to be able to effectively describe these difficulties for the affected individual themselves, families, and professionals; this leads to a better understanding of the person’s behaviors and the reason for them. This is likely to be particularly important for individuals who may benefit from specific intervention and resources, for example, mentoring in the workplace for adults with BAP and support from education and/or social care professionals for affected children, young people, and adults (see Parr et al. 2011; Parr and Le Couteur 2011).

Finally, relatively little is known about the neurobiology or pathophysiology of the BAP. It has been hoped that better understanding the BAP will lead to improved neurobiological knowledge about ASD itself. However, in keeping with ASD, replicated neurobiological findings are scarce (comprehensively recently reviewed by Lainhart and Lange 2011). Whether BAP will play a significant role in advancing our understanding of the complexity of ASD remains to be seen (Parr et al. 2011).

Future Directions

During the next decade, studies of parents and other relatives of people with ASD will continue, and this will undoubtedly expand the understanding of subclinical ASD traits. Genetics research is

likely to continue to be a major “driver” of increased knowledge about BAP, for example, there will be great interest in the extent to which the BAP is seen in the relatives of people with ASD who have an identified inherited or de novo causal variant as this will further inform our knowledge of the genetic and environmental contributions to ASD.

Another exciting prospect will be the findings from studies of siblings of children with ASD (“at-risk” or “high-risk” sibling studies). These studies will provide insights into the developmental trajectories of children with ASD and those without ASD who have the BAP; both groups can be compared to siblings who develop typically and to controls. In the future, as “high-risk” siblings move toward and into adolescence and adulthood, the knowledge of how early development and subsequent characteristics relate to individual progress and outcomes will improve.

Finally, one new direction for BAP research relates to intervention. There is currently great interest in whether intervention changes the developmental trajectories and outcomes for “at-risk” siblings (e.g., the study of Green and colleagues in the UK). Projects evaluating the effect of the BAP on the delivery of parent-mediated early intervention for ASD have commenced. If research findings show that the BAP has a negative impact on the effectiveness of parents’ interactions with their child with ASD, identifying the most beneficial intervention strategies for BAP-affected parents will become both a research and a clinical priority to ensure better understanding and effective targeting of evidence-based interventions.

For older children and adults with the BAP, interventions and treatments need to be evaluated. Researchers are, for example, beginning to investigate whether behavioral interventions such as social skills training or social stories might improve the social skills of people with BAP. Indeed, it could be argued that people with BAP might be more responsive to such interventions than individuals with a clinical diagnosis of ASD as they are less likely to have cognitive impairment, will have milder social impairment, and

may well have more insight into their difficulties. Workplace interventions for people with BAP may also be of benefit – whether mentoring or other types of workplace support give adults a greater chance of working more productively with colleagues still remains to be seen.

Broca's Aphasia

Elizabeth R. Eernisse

Department of Language and Literacy, Cardinal Stritch University, Milwaukee, WI, USA

Synonyms

[Nonfluent aphasia](#)

Short Description or Definition

Broca's aphasia is a language disorder that is characterized by limited, "telegraphic" spoken language output in the face of intact language comprehension skills. This condition is typically the result of damage to the left frontal lobe of the brain, often due to stroke, but may also result from traumatic brain injury or a degenerative neurological condition.

Categorization

Broca's aphasia is considered a "nonfluent" aphasia under larger aphasia classification systems due to the patient's lack of fluent speech output.

Epidemiology

Estimates of Broca's aphasia in the larger population are largely unknown, though it has been estimated that 80,000 people develop aphasia in the United States each year.

Natural History, Prognostic Factors, and Outcomes

The prognosis for individuals who are diagnosed with Broca's aphasia is largely dependent upon the severity of the condition. Often, people with Broca's aphasia do not completely recover fluent spoken language skills and need to develop compensatory strategies to manage the condition. It is thought that recovery is enhanced depending upon factors such as age of onset, health, education level, and how soon treatment takes place after brain damage has occurred.

assisting individuals with Broca's aphasia to transmit messages.

Family member and patient support groups are often a critical piece of the therapeutic process as the patient and family learn to manage the patient's changed mode of communication. Support groups are often key to recovery.

Please see ► [“Aphasia”](#) for a list of general treatment strategies for aphasia.

See Also

► [Aphasia](#)

Clinical Expression and Pathophysiology

Broca's aphasia is often due to damage in the left frontal lobe of the brain, also referred to as “Broca's area.” Patients demonstrate impaired, effortful speech/language output in the face of relatively intact comprehension skills.

Evaluation and Differential Diagnosis

Please see ► [“Aphasia.”](#)

Treatment

Treatment for Broca's aphasia, as in other aphasias, is typically individualized and is based on the patient's profile of strengths and needs. Formal speech-language therapy is often recommended to address functional communication in a variety of settings in which patients are expected to communicate. Therapy goals are focused on maximizing the individual's ability to communicate effectively with peers and family members, given residual strengths. For individuals with Broca's aphasia, treatment strategies often focus on language output and naming as well as building sentence length, building on their intact comprehension skills. In addition, computer-assisted methods are beginning to show promise in

Brodmann's Area 4

► [Precentral Gyrus](#)

Brodmann's Areas

Kartik Pattabiraman
Child Study Center, Yale School of Medicine,
New Haven, CT, USA
Department of Psychiatry, Yale School of
Medicine, New Haven, CT, USA

Definition

Brodmann's areas (BA) are regions of the cerebral cortex defined by the layer-specific organization of cells. These areas were originally annotated by German neurologist Korbinian Brodmann using basic staining techniques and microscopy in 1909. He initially divided the human cortex into 43 distinct areas. Later studies confirmed these boundaries and identified the functional significance of each area. For example, BA 44 and 45 are part of the left frontal cortex and are important for the motor aspect of speech. Several BAs have been implicated in autism including BA9 (dorsolateral prefrontal cortex), BA 24 (right anterior cingulate gyrus), and BA44 (left inferior frontal gyrus).

Bruininks-Oseretsky Test of Motor Proficiency

Mikle South and Jessica Palilla
Departments of Psychology and Neuroscience,
Brigham Young University, Provo, UT, USA

Synonyms

[BOT-2](#); [BOTMP](#)

Definition

The original version of the Bruininks-Oseretsky Test of Motor Proficiency was abbreviated as the BOTMP. The revised second edition is usually referred to as the BOT-2.

Description

The BOT-2 is designed to assess motor proficiency in children and adults from ages 4 to 21 years and 11 months. This was intended to cover the age range for children served by the American Individuals with Disabilities Education Act (IDEA). It is individually administered, standardized, and norm referenced. It is used for treatment planning and evaluation in clinical and school settings as well as for research. Physical and occupational therapists especially may find the test useful.

The Complete Form version of the BOT-2 includes 53 items based on activities such as cutting out a circle, copying a square, bouncing a ball, and standing on one leg. Items are organized into eight subtests and further categorized into four motor area composites and one comprehensive score. These composites are *strength and*

agility (running speed and agility + strength subtests, meant to measure control of the musculature of body involved in movement); *manual coordination* (manual dexterity and upper limb coordination subtests, meant to measure the ability to manually manipulate objects and the level of coordination in the hands and arms); *body coordination* (bilateral coordination and balance subtests, to measure large musculature control of posture, balance, as well as the sequential and simultaneous coordination of the lower and upper limbs); and *fine manual control* (fine motor precision and fine motor integration subtests, to measure the level of control and coordination of the hand and fingers by looking at an individual's ability to grasp, draw, and cut with scissors).

The nature of the measure makes it fairly easy to administer, as children tend to enjoy performing the variety of activities involved in the testing. The BOT-2 revision has made it much more adaptive for younger children, for instance by increasing the number of blocks to string and adding the balance beam to walk on. The entire battery of tests can take an hour to administer, but a 14-item Short Form of the test is available which only requires 20 min. The short form accounts for 96.3% of the variability in children ages 3–5, so it can be used as a substitute for the complete battery when appropriate. The test manual provides many clear pictures of the tasks being completed. However, scoring of the test is time-intensive, taking at least 20 min according to Deitz et al. (2007). Deitz et al. note that scoring for the BOT-2, although improved over the BOTMP, nonetheless is tedious, sometimes confusing, and easy to make errors. Norm lookup tables are also difficult to use.

Historical Background

The BOTMP was originally developed in Russia by Oseretsky in 1923 (Oseretsky 1923). When it was translated into English by Doll in 1946 (Doll 1946), it was known as the “Oseretsky Test of

Motor Proficiency.” However, because the test had been based on Oseretsky's personal observations of children, it had many problems relating to its psychometric properties. Multiple revisions were made in order to increase the reliability and validity of the measure, and the BOTMP represents the culmination of these revisions. The BOT-2 was published in 2005 with updated and revised materials, items, scales, and norms.

Psychometric Data

Criticisms of the original BOTMP included concerns about the normative sample being racially homogenous and functioning at normal levels both intellectually and motorically. A child's ability to understand and respond to instructions may have confounded motor skill development. Factor analyses showed that 14 of the 17 *fine motor* ability items loaded at significant levels on the general motor ability factor, implying that the BOTMP was not a good stand-alone measure for assessing fine motor abilities and that the grouping of tests into fine and gross motor skills was problematic. The creators of the BOT-2 revision set out to address these and other issues.

The normative sample for the BOT-2 included 1520 individuals from ages 4 to 21, with greater age differentiation for normative comparisons in younger children (in 1-year increments) up to a 5-year age increment for the adult sample. It was targeted to US Census Data from 2001 and included about 11% of children with special education status. Separate clinical samples were tested for autism/Asperger's, developmental coordination disorder, and mild-to-moderate mental retardation.

Interrater reliability reported by the developers of the BOT-2 is above .90 for all but the fine motor scale (adjuster $r = .86$). Test-retest reliability is good for the Total Composite and the Short Form totals, but generally less good (with substantial variability) for the other scale composites and item analyses. Deitz et al. (2007) therefore

recommend that the Composite scores be used wherever possible and that reliance on subscale scores is inadvisable.

Test developers utilized Confirmatory Factor Analysis to document a good fit for the four-factor model of the BOT-2, better than the two-factor (Fine vs. Gross Motor) structure of the original BOTMP. The three clinical samples all scored significantly lower than the normative sample on both the Complete and Short forms. Convergent validity was strong for the original BOTMP (adjusted $r = .80$ for composite scores); the Peabody Test of Developmental Motor Skills – Second Edition (adjusted r s ranging from .51 to .75 for subscales); and the Test of Visual Motor Skills – Revised (comparison of relevant fine motor skills adjusted $r = .74$).

Statistical modeling by Wuang et al. (2009) on a sample of 446 children diagnosed with intellectual disability found that the *manual coordination* and *strength + agility composites* fit the whole sample better than the *fine motor* and *body coordination* composites, which fit the lower-functioning end of the sample better than the higher-functioning end. Their analysis suggested elimination and/or restructuring of a number of items and scales to improve both reliability and discriminant validity.

Clinical Uses

Deitz et al. (2007) note that the inclusion of 11% special education students in the normative sample makes the BOT-2 less likely than its BOTMP predecessor to score children with motor disabilities as significantly below average.

The BOTMP has been used to characterize motor problems in individuals diagnosed with Autism Spectrum Disorders. One study (Ghaziuddin and Butler 1998) compared BOTMP motor coordination between children diagnosed with autism, Asperger's syndrome (AS), and pervasive developmental disorder not otherwise specified (PDDNOS). Of the three groups, those with autism were the most clumsy, followed by those with AS

and then those with PDDNOS. However, there was not a significant difference between the autism group and the AS group. These results indicate that caution should be used before including clumsiness as a diagnostic criterion for only one of the disorders. Dewey et al. (2007), using the BOTMP Short Form, found particular impairment in gestural performance in ASD relative to other clinical groups (developmental motor coordination and ADHD). In the context of generally impaired motor performance for all the clinical groups, Dewey et al. suggest that gestural impairments in autism are not solely attributable to motor problems.

The test is also frequently used in studies of developmental coordination disorders, with a few studies of ADHD. There are very few published studies that have used the BOT-2 instead of the original BOTMP.

Sleep bruxism

Definition

Bruxism is the nonfunctional and involuntary grinding, gnashing, clenching, or tapping of teeth. Bruxism is considered to be common among individuals with developmental delays or disabilities, including those diagnosed with autism spectrum disorders. Bruxism is classified as nocturnal (occurring during sleep) or diurnal (occurring while awake). Bruxism can be audible when teeth are grinding or gnashing or inaudible when teeth are clenching. Many are not aware of their bruxism, but some will develop symptoms such as tooth sensitivity, headaches, or jaw pain. Bruxism is considered to be a psychophysiological and sleep disorder influenced by anatomical and biological (i.e., dental abnormalities), neurological (i.e., mental retardation), and/or psychological (i.e., stress, trauma, anxiety) factors. Studies examining effective treatments for bruxism in individuals with developmental disabilities are limited to date; however, dental-based approaches, biofeedback, behavior therapy, habit

reversal, and stress management appear to be common interventions.

Buckhannon Versus West Virginia Department of Health and Human Resources: Definition of Prevailing Party

Regina Gilroy

Quinnipiac University School of Law, Hamden, CT, USA

Definition

In General

The issue in this case was whether the prevailing party in a claim for violating the Americans with Disabilities Act (ADA) should be awarded attorney's fees under the catalyst theory. The Supreme Court, quoting Black's Law Dictionary 1145 (7th ed. 1999), defines "prevailing party" as "[a] party in whose favor a judgment is rendered, regardless of the amount of damages awarded (in certain cases, the court will award attorney's fees to the prevailing party)." The catalyst theory provides fees to a party where the case serves as a "catalyst" for legislative change. The Supreme Court ruled that the "catalyst theory" is not an appropriate basis for attorney's fees under certain civil rights cases, including under the ADA. The prevailing party is only entitled to attorney's fees when they are victorious in court and awarded a judgment in court.

Implications for ASD Students

Buckhannon has implications for those with ASD. First, in the case of discrimination under the ADA, parents may be less willing to bring cases because of the expense of bringing a lawsuit. The parent would not be guaranteed expensive attorney fees if they end up prevailing outside of a courtroom. Only cases heard in court would be awarded attorney's fees. Second, IDEA (Individuals with Disabilities Education Act) has made fees available to parents who win in either administrative or

judicial proceedings. If IDEA follows the *Buckhannon* decision, then this fee payment for parents would become obsolete if a case is heard in an informal proceeding or dismissed because of a change in law.

Litigation Strategies

Buckhannon specifically dealt with an assisted living facility which failed a fire inspection. *Buckhannon* was ordered to be shut down, but filed suit under the ADA. After filing suit, the state legislature removed the language that created the problem. But, because of the Supreme Court decision, *Buckhannon* was not entitled to an award of attorney's fees. Most special education cases settle either because of the speed necessary to allow the child to continue his/her education or the school district changes its behavior before a decision is even made. Under *Buckhannon*, parents would not be able to recover attorney fees. It might be more appropriate to try to mediate between the parents and school district, so that in the mediation agreement the parents can be entitled to some reasonable attorney's fees.

Short Description or Definition

Bullying is an aggressive behavior perpetrated by those who hold and/or try to maintain a dominant position over others (Morita 1985). It is intended to cause mental and/or physical harm or suffering to another: it is a repetitive behavior and almost always involves an imbalance of power between victim and perpetrator in which the victim is usually not able to defend himself/herself (Farrington 1993). Bullying is also the most common form of school violence.

Bullying can take various forms including: exclusion, verbal abuse, physical abuse, and/or coercion (Kim et al. 2004). Bullying may be “direct” or “indirect.” Direct bullying includes physical and verbal aggression, such as kicking, threatening, name-calling, and insulting. Indirect or covert/relational bullying includes social exclusion/isolation, such as ignoring, cliques, rumor-mongering, insulting, and humiliating with the spread of embarrassing information about an individual (van der Wal et al. 2003).

Students are involved in bullying as victims, perpetrators, victim-perpetrators, or bystanders. Victims may experience many forms of bullying with considerable variability in form. Some students may be involved in bullying as both a victim and perpetrator; that is, they are bullied by one student or a group of students and may also

individually or in a group bully other students (Schwartz 2000).

With recent advances in information technology, bullying has added cyberspace to the schoolyard and neighborhood as sites for bullying. In cyberspace, bullying can take place anonymously, without overtly identifying the perpetrators. Further, children or adolescents may not be safe from bullying even in their homes since unkind text messages, hateful e-mails, videos, or provocatively manipulated messages and materials can reach them 24 h per day, 7 days a week (Pridgen 2009).

Epidemiology/Clinical Expression

Children and adolescents with Autism Spectrum Disorder (ASD) have essential difficulty in reciprocal social interaction along with impairment in communication skills (American Psychiatric Association [APA] 1994; Caronna et al. 2008; Frith and Hill 2004; Gura et al. 2011; Kelly et al. 2008; van Roekel et al. 2010). These difficulties make those with ASD especially vulnerable for involvement with bullying as victims and/or perpetrators since bullying is a form of dynamic and complex social interactions (Cappadocia et al. 2011; Sharp and Cowie 1994). Children with ASD also often demonstrate stereotyped behavior and a limited range of interests, often in unusual topics or objects that can make them stand out as quite different from their peers: this often puts them in the position of becoming targets for ridicule (Cappadocia et al. 2011; Gray 2004). Other challenges often facing children with ASD that include unusual sensory responses such as hyper/hyposensitivity to auditory, olfactory, tactile, or visual stimuli; problems in motor coordination; and poor performance in physical education, can also contribute to the risk of becoming a target of the peer victimization (Bejerot et al. 2011; Kelly et al. 2008).

Perpetrators of bullying intend to cause mental and/or physical harm or suffering on other children; perpetrators identify what would cause pain to their victims and, then, plan and execute their actions accordingly. However, it is difficult for

children and adolescents with ASD to bully others due to their difficulties in understanding and using the rules governing social behaviors and perspectives of other people. Nevertheless, their behaviors may be regarded as bullying for several reasons. First, children and adolescents with ASD may have increased levels of aggressive behaviors (Mandell et al. 2005; van Roekel et al. 2010). Since bullying is a form of aggression, those with ASD who have increased level of aggression may be considered to be bullying other children or adolescents (van Roekel et al.). Second, because adolescents with ASD have limited insight into social processes (Frith and Hill 2004; van Roekel et al. 2010), they may not be aware of the consequences of their own behavior or words; some of these behaviors may be regarded as bullying (van Roekel et al.). For example, children with ASD may say brutally honest things or violate the physical space of others to the extent that they cause discomfort, even though it may not be intended to be bullying (Montes and Halterman 2007; van Roekel et al. 2010).

Although the severity of ASD symptoms is negatively correlated with successful social inclusion and peer relationships, even children and adolescents with high-functioning ASD continue to struggle with social competence as they age (Brauminger and Kasari 2000; Cappadocia et al. 2011; Orsmond et al. 2004); as a result, even with improvement in overall functioning, individuals with ASD remain at increased risks for bullying experiences (Cappadocia et al. 2011).

Indeed, several previous studies have reported that children or adolescents with ASD showed increased involvement in bullying as victims or perpetrators (Cappadocia et al. 2011; Little 2001, 2002; Twyman et al. 2010; van Roekel et al. 2010). Little used a website survey of 411 parents of children with Asperger's disorder (AD) (75% of subjects) or nonverbal learning disorder (25%); they reported that up to 75% of the children with AD were bullied within previous year. The younger children, boys, and children with ASD had greater risk for victimization (Little 2001). In another study of 187 adolescents with ASD attending a special secondary education school,

van Roekel et al. also reported that 7–30% were victimized more than once a month, and 19–46% bullied others, depending on the informants (teacher, peer, or self-report of bullying) (van Roekel et al. 2010). Samson et al. showed individuals with Autistic Disorder recruited from clinics in Germany and Switzerland (40 with autism and 83 control), who reported higher rates of experiencing teasing or being ridiculed, compared to the control group who did not have ASD diagnoses (Samson and Huber 2010). Interestingly, Shtayermann measured the bullying experiences of 10 adolescents or young adults with Asperger's Disorder using mailed or online self- or parent's questionnaires, and reported a negative correlation between the severity of AD symptoms and victimization. The authors considered that children and adolescents with milder AD symptoms received lesser support and supervision from teachers and/or parents than those with severe symptom, leading to greater risks for victimization due to "under-surveillance" by adults (Shtayermman 2007). Although there are significant limitations in his study, including the small number of samples and survey accuracy, this finding suggests that children and adolescents with ASD, irrespective of symptom severity, require appropriate support from caregivers and teachers in order to prevent peer victimization. Additionally, Volker et al., using a standardized behavioral rating scale, demonstrated that children and adolescent with high-functioning ASD recruited from those awaiting participating in social intervention study ($N = 62$) showed increased scores for bullying participation when compared to a control group, even after being controlled for their IQs (Volker et al. 2010).

When examining the experience of school bullying in children and adolescents with ASD, the school setting likely plays an important role: there are advantages and shortcomings in different school settings for children and adolescents with ASD (Burack et al. 1997; Laugeson et al. 2009). On one hand, regular classroom has been associated with increases in the complexity of interactions and decreases in nonsocial activity, in comparison to special education settings. On the other hand, these individuals report often feeling

lonelier and having poorer quality friendships than their typically developing classmates (Capps et al. 1996; Laugeson et al. 2009; Sigman and Ruskin 1999). Another study also implies important feature that in a special educational setting, teachers report higher rates of bullying among students with ASD than those without (van Roekel et al. 2010).

In general, bullying is associated with various psychological problems as consequences or antecedents to bullying experiences (Barker et al. 2008; Kim et al. 2005, 2006; Salmon et al. 1998; Srabstein and Piazza 2008); children and adolescents with ASD who are also involved with bullying are not exceptions. In a study of 192 children diagnosed with ASD recruited from the website for parents of children with ASD or the school system, using parental report of psychopathology, Cappadocia et al. reported that ASD children who were bullied once or more per week had higher levels of anxiety; hyperactivity; self-injurious, stereotypic behaviors; and oversensitivity when compared to those not bullied or bullied less than once per week (Cappadocia et al. 2011). Additionally, correlations between peer victimization and suicidal ideation were reported in adolescents with AD (Asperger's Disorder) (Shtayermman 2007).

Kelly et al. reported that peer victimization was not only directly related to severity of ASD symptoms, but also that poor peer relationship was associated with anxiety and depression symptoms measured by parental survey in 322 children with ASD recruited from the clinics. This suggests that not only do ASD symptoms increased risks for peer victimization but also that victimization may worsen associated symptoms in children with ASD (Kelly et al. 2008). Such bidirectional impacts of social problems and peer victimization on each other have been already demonstrated in a general population of adolescents in a longitudinal study (Kim et al. 2006).

In addition to ASD severity, cognitive function may play roles in the risks for the involvement in bullying and development of psychopathological consequences from bullying experiences. For example, children with milder forms of ASD or higher cognitive function may be more accurate in

recognizing bullying when they are bullied while those with more severe ASD or lower levels of cognitive function might not; this may lead to more serious adverse consequences from bullying experiences in the higher functioning groups (Sofronoff et al. 2011).

The experience of bullying in childhood and adolescence can have long-term sequelae, including in adulthood. Samson et al. recruited 40 adults diagnosed with ASD and 83 adults without ASD to compare their recollection of bullying experience in their childhood and/or youth; compared to the control group, the individuals with Asperger's Disorder report not only higher rates of recollections of being ridiculed or teased in their childhood or youth, but also fear for being ridiculed at present, indicating that the psychological damage of school bullying persists beyond the school years (Samson and Huber 2010).

Evaluation and Differential Diagnosis

Given the high prevalence of bullying and its association with psychiatric and psychological morbidities in children and adolescents with ASD, comprehensive and careful attention and assessment is required for prevention, early identification, and intervention with bullying in ASD children and adolescents.

Due to their impairments in making and recognizing social interactions, the utility of self-report as a tool for identifying bullying experiences in the ASD population may be limited. Indeed, van Roekel et al. showed that teachers reported higher prevalence of bullying compared to peer- and self-reports which indicated much lower rates of school bullying in this population: teachers reported 27% of adolescents frequently involved in school bullying (more than once a week), whereas adolescents themselves reporting only 12% in 230 adolescents with ASD (van Roekel et al. 2010). This was distinctly different from the findings in children and adolescents without ASD, when on average self-report or peer nomination measurement report 35–48% of involvement in bullying as victims and/or perpetrators, but teacher or parent report only have 10–18%

(Cleary 2000; Hunter et al. 2004; Ladd and Kochenderfer-Ladd 2002; Nansel et al. 2001; Rønning et al. 2009). Such a discrepancy may stem from the combination of two factors: First, teachers may have missed opportunities to witness bullying incidences among typically developing children since bullying usually occur in the absence of adults supervision; children and adolescents with ASD receive higher levels of supervision and monitoring from teachers, resulting in more opportunities for teachers to observe peer interactions and bullying in this population. Second, individuals with ASD have difficulties understanding the mental states of other people, and consequently in understanding the intentions of others (Frith and Hill 2004; van Roekel et al. 2010). It may be difficult for children and adolescents with ASD to recognize or identify bullying incidents due to their limited social insights, unlike typically developing children (van Roekel et al.). Therefore, comprehensive assessment with multiple informants including caregivers, teachers, and peers in addition to self-report is crucial for the identification of bullying experience in children and adolescents with ASD (Ladd and Kochenderfer-Ladd 2002; Mandell et al. 2005).

Treatment

Screening for bullying experience and symptoms for ASD in primary care and community setting is an important first step for early identification and intervention since children and adolescents with ASD are at increased risks for the involvement of bullying (Gura et al. 2011; Tantam and Girgis 2009).

Careful school placement is crucial for children and adolescents with ASD. Regular education classroom placement has resulted in mixed outcomes for individuals with ASD (Burack et al. 1997; Laugeson et al. 2009). As mentioned earlier, mainstream classroom placement is associated with the increase of the complexity of interactions and decrease in nonsocial activity in comparison to special education. On the other hand, placement in special education classroom can enhance teachers' capacities for careful

attention and intervention for those students with ASD and protection from undesirable social stigma and traumatization (Laugeson et al.). Having close friends in a classroom is protective of becoming a target of bullying (Cappadocia et al. 2011; Nansel et al. 2001; Williams and Guerra 2007). Therefore, interventions such as social skill training to help these children have better friendship will decrease their risks for peer victimization (Laugeson et al. 2009).

Children and adolescents with ASD have various comorbid psychopathologies including depression, anxiety, and withdrawal, which are reported to be associated with increased risks for the involvement of bullying in general population (Volker et al. 2010). Appropriate assessment and interventions for comorbid conditions in ASD children is warranted (Volker et al.).

When a child is being bullied, particularly a child with a disability, adult support is crucial. Through scaffolding, adults can support children to acquire and develop important social skills such as: adaptive emotional and behavioral regulation strategies and coping skills, identifying and engaging with supportive peers, problem solving, and communicating assertively (Cappadocia et al. 2011; Cummings et al. 2006). Recent research supports the effectiveness and importance of parent-assisted learning with respect to developing social skills among children with ASD (Cappadocia et al. 2011; Frankel et al. 2010; Laugeson et al. 2009). This relationship scaffolding, individualized for each child to capitalize on his or her strengths and support weaknesses, can help the child develop coping skills that may reduce the impact of the bullying on the victimized child and in turn reduce the likelihood of bullying. It is important to encourage children to seek help from a trusted adult and continue to seek help until they find an adult who is willing to listen and offer protection and support. Once the adult understands the particulars of the bullying episodes (e.g., when and where), safe places and safe people can be discussed to minimize the risk for bullying to occur (Cappadocia et al. 2011; Cummings et al. 2006).

Finally, validated effective antibullying campaigns/interventions to decrease bullying in

home, schools, and communities will exert preventive effect on bullying not only for children with ASD but for all children receiving such interventions (Olweus 1994; Olweus and Limber 2010; Vreeman and Carroll 2007).

Understanding the relationships between ASD and bullying has been limited due to the shortcomings of previous studies, including small sample size, limited sampling methods, and/or inadequate measurement of bullying (Mandell et al. 2005). Future study should focus on incidence/prevalence of bullying, the impact of bullying experiences on the natural course of ASD, associations between bullying experiences and other comorbid psychopathology, and development and assessment of intervention programs in larger population-based samples of children and adolescents with ASD.

Conclusion

Bullying is common among all children, but the children with ASD are at even greater risk of this harmful experience. And, just as is the case for typically developing children, reduction of bullying enhances developmental prospects for all children, including those with ASD. While ASD may not be preventable at this time, we can reduce or even prevent bullying experiences for children with ASD, as we can and must for all children.

Bupropion

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Synonyms

[Wellbutrin](#); [Zyban](#)

Definition

Bupropion is a novel antidepressant that is believed to block reuptake of dopamine. It is indicated for the treatment of depression ([Wellbutrin](#)) and for smoking cessation ([Zyban](#)). It has also been evaluated as a treatment for attention deficit/hyperactivity disorder in children and adults. It has not been evaluated systematically in children or adults with autism.

Synonyms

[Buspar](#); [Vanspar](#)

Definition

Buspirone is an antianxiety medication that is an agonist for serotonin 1A receptor. Unlike benzodiazepines, buspirone does not directly affect a GABA system and is not habit-forming. There is limited information on the use of buspirone in children and only one trial in adolescents with pervasive developmental disorders. In that study, buspirone appeared to be only modestly beneficial for disruptive and agitated behavior.

California Verbal Learning Test, Children's Version (CVLT-C)

Beau Reilly and Raphael Bernier
Psychiatry and Behavioral Sciences, University of
Washington, Seattle, WA, USA

Synonyms

[CVLT – Children's Version](#); [CVLTC](#); [CVLT-C](#)

Description

The California Verbal Learning Test-Children's Version (CVLT-C; Delis et al. 1994) is an examination of auditory and verbal learning for children between the ages of 5 years and 16 years 11 months. The test makes use of familiar visual categories to generate a measure of short- and long-term memory performance. Encoding and recall are examined via the use of single words verbally presented in the context of “a shopping list” over the course of eight total trials spanning

15–20 min with an additional 20-min period to accommodate delayed recall testing.

During the first five trials of CVLT-C, a list of 15 items consisting of three semantic categories (fruit, clothing, and toys), labeled “list A” or “the Monday list,” is read aloud to the child and he or she is asked to recall as many items as possible following each presentation. During the sixth trial, a second 15-item list containing new words that belong to one of the categories from the original list (fruits) as well as words from two new categories with semantic similarities (furniture and sweets) from the original list are presented as “list B” or “the Tuesday list” to the child as an interference task. The child is then asked to recall as many words as possible. After completion of the list B trial, the child is then asked to recall words from list A without presentation of the items. In the seventh trial, list categories are used as cues to elicit recall from the original list via prompts from the examiner such as “Tell me all the things to wear in the Monday list.” Following trial 7 is a 20-min break from the task during which time the child can complete nonverbal tasks or participate in other activities that provide moderate distraction. Following this “long-delay” interval, the child is asked to recall as many words as he or she can from list A (long-delay free-recall trial), asked to recall words from list A after being provided with the categorical cues (long-delay cued-recall trial), and finally read a 45-item list aloud and asked to indicate whether

or not each word was on list A (yes/no recognition trial). Responses are recorded and documented by the examiner during every trial.

A complete administration of the CVLT-C produces data on eight recall measures, eight learning characteristics, four areas of recall errors, four recognition measures, and five contrast measures. This includes information concerning encoding strategies for success over time as well as the characteristics of errors that occur. In addition to generating information on the quantity of items accurately recalled after each of the eight testing trials, the CVLT-C allows for the detailed examination of characteristics related to acquisition methods utilized during the learning process. Characteristics related to the learning process are examined through the use of learning strategy variables and contrast variables.

The learning strategy variables aid in outlining the characteristics of acquisition and encoding that progress throughout the course of the examination. They include semantic clustering (i.e., consecutive words from the same category), serial clustering (i.e., words recalled in the same order in which they were presented), primacy recall (i.e., percentage of words recalled from the first five items of the list), middle recall (i.e., percentage of words recalled from the middle five items of the list), recency recall (i.e., percentage of words recalled from the last five items of the list), learning slope (i.e., the average number of new words recalled per learning trial), consistency (i.e., percentage of words recalled once that were also recalled on the following trial), recognition hits (i.e., number of words correctly identified as belonging to list A during the recognition trial), and discriminability (i.e., accuracy of distinguishing target words in list A from distraction words in list B). Characteristics of errors are also calculated with regard to perseveration (i.e., words repeated in a trial), free intrusions (i.e., extra-list intrusions on all free-recall trials), cued intrusions (i.e., extra-list intrusions on the cued-recall trials), total intrusions (i.e., extra-list intrusions on all trials), false-positives (i.e., words incorrectly identified as list A items during the recognition trials), and response bias (i.e., the tendency to identify words as belonging on the

target list during recognition trials). The learning slope variable, in particular, allows for a thorough examination of specific learning characteristics that may be evident across differing presentations of clinical populations. Deficits in areas related to learning (i.e., flat learning slope across trials with low amounts of new words learned), encoding (e.g., poor trial 1 performance followed by a normative learning slope), or sustaining focus (i.e., normative recall on initial trials with poor recall on later trials) can be identified with the learning slope, allowing for the closer inspection of learning characteristics and discrimination of other possible domains of learning that may be affected (Spren and Strauss 1998). Children with Down syndrome, attention deficit hyperactivity disorder (ADHD), and other disorders have demonstrated distinct and differentiated characteristics of learning slope in clinical populations (Delis et al. 1994).

The CVLT-C contrast variables (Donders 1999) aid in the identification of trial discrepancies and learning differences that occur throughout the learning process. These include aspects of encoding related to proactive interference (i.e., the contrast between list B recall and list A trial 1 recall), retroactive interference (i.e., the contrast between list A short-delay free recall and list A trial 5), rapid forgetting (i.e., contrast between list A long-delay free recall and list A short-delay recall), and retrieval problems (i.e., contrast between discrimination trial and list A long-delay free recall).

Historical Background

Delis et al. (2000) observed that while there are a variety of verbal learning instruments that measure the amount of material that is recalled, far fewer examine the processes by which the information is learned and retrieved. Construction of CVLT-C in 1994 followed the same process-oriented approach of the original California Verbal Learning Test (CVLT) for adults (Delis et al. 1987). For construction of the task, selection of the target words themselves was chosen based on their frequency of occurrence in the English

language as well as the frequency of reported words by children in the sample. The three most common words in each semantic category were removed to avoid recall confounds associated with item familiarity (Miller et al. 2003). The context of a shopping list was selected for its consistent familiarity with children across a wide range of cultural and demographic variables and mapped closely with the CVLT with regard to presentation, timing, and scoring.

Psychometric Data

The normative sample for the CVLT-C consists of stratified data taken from the 1988 US census findings and is comprised of 920 children in 12 age ranges from 5 years to 16 years 11 months. Standardized scores were derived from accumulative raw score performance per age group, distribution normalization, and elimination of outliers and skewing effects. The remaining learning score components of the CVLT-C were developed via regression analyses (Delis et al. 1987).

Investigations of test-retest reliability among 106 school-age children ranged from .17 (cued-recall intrusions, for 12-year-olds) to .90 (perseverations, for 8-year-olds) (Delis et al. 1987, 1994; Spreen and Strauss 1998). Alternate forms reliability was reported at .84 (Delis et al. 1987, 1994; Spreen and Strauss 1998), indicating appropriate reliability for multiple administrations with children and tracking results and learning characteristics over time.

Gender effects were reported by the authors to be minimal in the initial standardization sample, and significant differences were not found for gender in the 4-year-old sample norms provided by Goodman, Delis, and Mattson (Goodman et al. 1999) for normative populations. However, differences in gender have been reported in follow-up examinations of the standardization sample (Kramer et al. 1997) and have been evidenced in clinical populations of children with ADHD (Cutting et al. 2003) and significant head injury (Warschausky et al. 2005). Gender effects were also evident in examinations of adolescent populations, with girls outperforming boys

(Beebe et al. 2000). Low correlations with measures of executive functioning and moderate associations with intelligence measures such as the Wechsler block design and vocabulary subtests have been reported (Beebe et al. 2000). Donders (1999) also identified a significant link between parental education levels and test performance in the standardized sample, with children of parents with higher education consisting of 22% of the highest performing children and children of parents with lower rates of education accounting for 30% of the children in the below-average range of performance.

Predictably, age effects were observed among the standardization sample, with steeper learning slopes being present in children as age increased and development progressed. Consistency of recalled items and immediate recall scores were also observed to have developmental trends across the sample. The use of semantic clustering strategy as a learning strategy was first emergent among 9–12-year-old participants. Adolescents in the sample exhibited higher degrees of serial clustering strategy use compared to other age groups (Delis et al. 1994). Investigations of executive functioning and CVLT-C process scores further indicate that perseverative errors evidence strong consistency throughout development with minimal improvement, while rates of intrusions and false-positives exhibit considerable improvement as development progresses into adolescence (Beebe et al. 2002; Delis et al. 1994).

Donders (1999) provided maximum likelihood confirmatory factor analysis on 13 qualitative and quantitative variables from the original standardized sample to identify the most salient factors of learning and memory tapped by the CVLT-C. A five-factor model consisting of attention span, learning efficiency, free delayed recall, cued delayed recall, and inaccurate recall showed the greatest fit and was proposed to be a valid and clinically useful predictor of performance on the measure.

The CVLT-C has been co-normed with the children's category test (CCT; Boll 1993), allowing examiners to compare a child's memory and learning performance with other forms of higher order cognitive functioning. Combining the

results of both tasks to generate the learning profile of a child can be clinically valuable as the CCT provides explicit feedback on a nonverbal task, while the CVLT-C provides non-explicit feedback on a verbal task through repetition. By taking advantage of the co-normed scores, clinicians are able to tap a wider range of learning areas and skills for characterizing the cognitive capabilities of the child. Donders (1999) examined the psychometric comparisons of the two measures including the magnitude of difference necessary for statistical significance in scores. Standardized sample data from both measures were used to evaluate covariances and statistically significant discrepancies between the T scores of those instruments as well as the base rate of specific discrepancies among 920 children ranging in age from 5 to 16 years. Results suggested that the CCT and CVLT-C share a small degree of common variance. Statistically significant score discrepancies between the two measures (T-score difference greater than 18 among 5–8-year-olds and greater than 16 among 9–16-year-olds) were common, indicating that evaluation of the potential clinical significance of a discrepancy between the obtained results should also include consideration of base rate statistics when evaluating individual children.

While the standardization sample focused on children ages 5 years through 16 years 11 months, Goodman et al. (1999) provided normative data for 4-year-old participants on the CVLT-C for potential administration with younger populations to aid in early identification and intervention. Each month of the 4-year-old range was represented among the stratified sample of 80 (40 males and 40 females). Performance characteristics of the younger population were considerably similar to that of the normative sample data, apart from a few learning characteristics. The 4-year-old participants had a tendency for higher extra-list intrusions relative to their correct responses on cued recall that were not present on free recall as well as a higher endorsement of distracter items during the recognition trial. Semantic and serial clustering characteristics were also consistent with developmental trends, providing evidence for utility in identifying early

memory and learning characteristics with the younger population.

Clinical Uses

The CVLT-C has been used to assess memory and learning in a wide variety of clinical childhood populations and has been used to examine verbal learning in children with ASD. Early studies of memory and list learning among children with ASD highlighted specific deficits in recall compared to control groups. Boucher and Warrington (1976) used memory tests that employed pictures, lists, and spoken words with 29 children with ASD and compared recall scores against age-matched controls. During trials of forced-choice recall, children with autism showed significantly lower rates of recall than controls but demonstrated considerable improvement when provided with semantic descriptive cues of list items and pictures.

Initial investigations of verbal recall among children with autism spectrum disorder (ASD) utilizing the CVLT also suggested distinct differences in learning and memory profiles when compared to typically developing peers. Minshew and Goldstein (1993) compared the performance of high-functioning children and adults with ASD ranging in age from 12 to 40 years old to age-matched normal controls using the CVLT. The comparison group significantly outperformed the ASD group. Specific scores indicated that while individuals with ASD showed comparable recall and recognition scores when presented with list A of CVLT, they showed significantly more intrusion errors on both list A and list B items and considerably lower recall scores on list B. The authors concluded that the overall characteristics of the ASD scores were indicative of a “subtle inefficiency of verbal memory” that was more suggestive of deficits in mechanisms for effectively organizing information than a reflection of comprehensive memory impairment.

More recent investigations into learning strategies and encoding profiles of children with ASD lend support for this theory and suggest that the CVLT-C may be effective in highlighting specific

characteristics of verbal learning in children with ASD that differ from those of typical developing peers. Phelan, Filliter, and Johnson (Phelan et al. 2010) compared performance and verbal learning characteristics on the CVLT-C between 15 high-functioning children with ASD and typical developing controls. Although the learning profiles and performance characteristics of both groups were comparable, children with ASD demonstrated considerable improvement in their cued-recall scores compared to their free-recall scores, suggesting the need for external supports and cueing opportunities to facilitate verbal memory performance among ASD youth.

Key clinical strengths of the CVLT-C include its relative ease of use and excellent internal consistency. Considerable research and psychometric data have been gathered with CVLT-C, and it has proven useful in predicting a variety of difficulties and deficits that can inform decision making concerning placements in groups such as head trauma patients and other neurodevelopmental disorders (Nagel et al. 2006; Nichols et al. 2004). As previously noted, the test provides a considerable amount of information about the verbal learning process and learning strategies across a relatively short period of time in such a way that recall and cueing effects can be examined efficiently and reliably. Scores on the CVLT-C have been shown to account for a considerable amount of the variance in the prediction of special education services and long-term educational outcome among children with severe head injury that could translate to other clinical populations (Miller and Donders 2003). The CVLT-C's implementation across a wide range of childhood populations illustrates its breadth in utility and efficiency across several domains of care. The provision of normative data for 4-year-olds additionally provides valuable opportunities for early screening, intervention, and tracking among children early in development. While the internal consistency of the test has been thoroughly investigated and validated, stability coefficients of many of the variables examined in the CVLT-C fall below acceptable standards, cautioning against the use of single variables as valid examination of cognitive factors (Spreen and

Strauss 1998). Overall, the test has shown to be an efficient and informative instrument of memory and verbal learning among children that serves as a valuable asset to clinicians involved in diagnostic assessment, treatment planning, service enrollment, and needs assessment.

CANTAB

Description

The CANTAB[®] tests are simple, computerised, non-linguistic, and culturally blind. They can be

administered by a trained assistant. Importantly, interpretation of a patient’s condition can be easily understood by a clinician. Below is a complete list of all tests, correct at time of publication. The tests are categorised as assessing the following cognitive domains:

1. Induction
2. Visual Memory
3. Executive function
4. Attention
5. Verbal/Semantic Memory
6. Decision Making and Response Control
7. Social Cognition
8. Other tests

CANTAB – Induction

These very short tests can be used to familiarize participants with the general idea of responding in a task by touching the screen. They can also be regarded as warm-up tasks, getting the participant used to the general testing situation.

They consist of: Motor Screening Task and Big/Little Circle.

Motor Screening (MOT)

See Fig. 1.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 1 Motor screening task

Overview

The Motor Screening test is typically administered at the beginning of a test battery, and serves as a simple introduction to the touch screen for the participant. If a participant is unable to comply with the simple requirements of this test, it is unlikely that they will be able to complete other tests successfully. This test therefore screens for visual, movement, and comprehension difficulties.

Administration Time

Around 2 min

Task

Participants must touch the flashing cross which is shown in different locations on the screen.

Outcome Measures

This test has two outcome measures which measure the participant's speed of response and the accuracy of the participant's pointing.

Test Modes

Two modes are available – clinical and high visibility. In high visibility the crosses are drawn using thicker lines and are easier to see.

Big/Little Circle (BLC)

See Fig. 2.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 2 Big/Little circle (BLC)

Overview

The Big/Little Circle test assesses comprehension, learning, and reversal. It is also intended to train participants in the general idea of following and reversing a rule, before proceeding to the *Intra-Extra dimensional Shift test (IED)*, so it should ideally precede the IED task in a battery.

Administration Time

Around 2 min.

Task

Participants must first touch the smaller of the two circles displayed, then, after 20 trials, touch the larger circle for 20 further trials.

Outcome Measures

This test has five outcome measures, covering latency (speed of response) and the participant's ability to touch the correct circle.

Test Modes

One mode – clinical

Visual Memory

These tests allow investigation of visual and spatial aspects of memory and consist of: Delayed Matching to Sample, Paired Associates Learning, Pattern Recognition Memory and Spatial Recognition Memory.

Delayed Matching to Sample

See Fig. 3.

Overview

Delayed Matching to Sample (DMS) assesses forced choice recognition memory for novel non-verbalisable patterns, and tests both simultaneous and short-term visual memory. This test is primarily sensitive to damage in the medial temporal lobe area, with some input from the frontal lobes.

Administration Time

Around 10 min

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 3 Delayed matching to sample

Task

The participant is shown a complex visual pattern (the sample) and then, after a brief delay, four similar patterns. The participant must touch the pattern which exactly matches the sample.

Outcome Measures

This test has 19 outcome measures, assessing latency (the participant's speed of response), the number of correct patterns selected, and statistical analysis measuring the probability of an error after a correct or incorrect response.

Test Modes

Clinical mode (for testing once); five parallel modes (for repeated testing), and child mode (a simplified version for testing children)

Paired Associates Learning (PAL)

See Fig. 4.

Overview

This challenging test assesses visual memory and new learning, and is a useful tool for assessing patients with questionable dementia, Mild Cognitive Impairment, Alzheimer's disease, and age-related memory loss.

Administration Time

Around 10 min, depending on level of impairment

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 4 Paired associates learning (PAL)

Task

Boxes are displayed on the screen and are opened in a randomized order. One or more of them will contain a pattern. The patterns are then displayed in the middle of the screen, one at a time, and the participant must touch the box where the pattern was originally located. If the participant makes an error, the patterns are re-presented to remind the participant of their locations. The difficulty level increases through the test. In the clinical mode, the number of patterns increases from one to eight, which challenges even very able participants.

Outcome Measures

This test has 21 outcome measures, covering the errors made by the participant, the number of trials required to locate the pattern(s) correctly, memory scores, and stages completed.

Test Modes

Clinical mode (for testing once); five parallel modes (for repeated testing)

Pattern Recognition Memory (PRM)

See Fig. 5.

Overview

This is a test of visual pattern recognition memory in a two-choice forced discrimination paradigm. This test is often used, in conjunction with *Spatial Recognition Memory (SRM)*, before the *Paired*

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 5 Pattern recognition memory

Associates Learning (PAL) test, as both these tests help to train the participant for PAL.

PRM and SRM contain different elements of PAL and the results considered together help to decide on the exact nature of the cognitive deficit being considered.

Administration Time

Around 5 min, depending on level of impairment

Task

The participant is presented with a series of 12 visual patterns, 1 at a time, in the center of the screen. These patterns are designed so that they cannot easily be given verbal labels. In the recognition phase, the participant is required to choose between a pattern they have already seen and a novel pattern. In this phase, the test patterns are presented in the reverse order to the original order of presentation.

This is then repeated, with 12 new patterns. The second recognition phase can be given either immediately or after a 20 min delay.

Outcome Measures

This test has three outcome measures, including the number and percentage of correct trials and latency (speed of participant's response).

Test Modes

Clinical mode (for testing once); four parallel modes (for repeated testing). Each of these

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 6 Spatial recognition memory

modes also has separate immediate and delayed versions available.

Spatial Recognition Memory (SRM)

See Fig. 6.

Overview

This is a test of visual spatial recognition memory in a two-choice forced discrimination paradigm. This test is often used, in conjunction with *Pattern Recognition Memory (PRM)*, before the *Paired Associates Learning (PAL)* test, as both these tests help to train the participant for PAL.

PRM and SRM contain different elements of PAL and the results considered together help to decide on the exact nature of the cognitive deficit being considered.

Administration Time

Around 5 min, depending on level of impairment

Task

The participant is presented with a white square, which appears in sequence at five different locations on the screen. In the recognition phase, the participant sees a series of five pairs of squares, one of which is in a place previously seen in the presentation phase. The other square is in a location not seen in the presentation phase. As with the PRM test, locations are tested in the reverse of the presentation order. This subtest is repeated three more times, each time with five new locations.

Outcome Measures

This test has three outcome measures, including the number and percentage of correct trials and latency (speed of subject's response).

Test Modes

Clinical mode (for testing once); four parallel modes (for repeated testing)

CANTAB – Executive Function, Working Memory, and Planning Tests

These tests address executive function, working memory, and planning; all are associated with the frontal area of the brain.

Attention Switching Task (AST)

Overview

AST is a test of the participant's ability to switch attention between the direction or location of an arrow on screen. This test is a sensitive measure of frontal lobe and 'executive' dysfunction.

Administration Time

Around 8 min, depending on level of impairment

Task

The test begins with an arrow in the centre of the screen which points either to the left or to the right. The participant is introduced to two buttons, one on the left and one on the right, and is asked to press a button corresponding to the direction in which the arrow is pointing.

After this initial training, the participant is then told that the arrow might appear on the left or the right side of the screen, and depending on the cue given at the top of the screen, the participant must either press the left or right button to indicate on which side of the screen the arrow is displayed, or else press the left or right button to correspond with the direction in which the arrow is pointing.

Outcome Measures

AST has 7 outcome measures, each of which can have various options applied to it. The AST measures cover latency, correct and incorrect

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 7 Intra-extra dimensional set shift

responses, commission errors, omission errors, switch cost and congruency cost.

Test Modes

AST has one mode: Clinical

Intra-Extra Dimensional Set Shift (IED)

See Fig. 7.

Overview

Intra-Extra Dimensional Set Shift is a test of rule acquisition and reversal. It features:

- Visual discrimination and attentional set formation
- Maintenance, shifting, and flexibility of attention

This test is primarily sensitive to changes to the fronto-striatal areas of the brain.

This test is a computerized analogue of the Wisconsin Card Sorting test, and is sensitive to cognitive changes associated with schizophrenia, Parkinson's Disease, and dopaminergic-dependent processes.

Administration Time

Around 7 min, depending on level of impairment

Task

Two artificial dimensions are used in the test:

- Color-filled shapes
- White lines

Simple stimuli are made up of just one of these dimensions, whereas compound stimuli are made up of both, namely white lines overlying color-filled shapes. The participant starts by seeing two simple color-filled shapes, and must learn which one is correct by touching it.

Feedback teaches the participant which stimulus is correct, and after six correct responses, the stimuli and/or rules are changed. These shifts are initially intra dimensional (e.g., color-filled shapes remain the only relevant dimension), then later extra dimensional (white lines become the only relevant dimension).

Participants progress through the test by satisfying a set criterion of learning at each stage (six consecutive correct responses). If at any stage, the participant fails to reach this criterion after 50 trials, the test terminates.

Outcome Measures

This test has 18 outcome measures, assessing errors, and number of trials and stages completed.

Test Modes

Clinical mode (for testing once); seven parallel modes (for repeated testing)

One Touch Stockings of Cambridge (OTS)

See Fig. 8.

Cambridge Neuropsychological Test Automated Battery, Fig. 8 One touch stockings of cambridge

Overview

One Touch Stockings of Cambridge is a spatial planning task which gives a measure of frontal lobe function. OTS is a variant of the *Stockings of Cambridge* test (see below) and places greater demands on working memory as the participant has to visualize the solution.

Administration Time

Around 10 min, depending on level of impairment

Task

As for SOC (Stockings of Cambridge), the subject is shown two displays containing three colored balls. The displays are presented in such a way that they can easily be perceived as stacks of colored balls held in stockings or socks suspended from a beam. This arrangement makes the 3-D concepts involved apparent to the participant, and fits with the verbal instructions.

There is a row of numbered boxes along the bottom of the screen. The test administrator first demonstrates to the participant how to use the balls in the lower display to copy the pattern in the upper display, and completes one demonstration problem, where the solution requires one move. The participant must then complete three further problems, one each of two moves, three moves, and four moves.

Next the participant is shown further problems, and must work out in their head how many moves the solutions to these problems require, then touch the appropriate box at the bottom of the screen to indicate their response.

Outcome Measures

OTS has four outcome measures – problems solved on first choice, mean choices to correct, mean latency to first choice, and mean latency to correct. Each of these measures may be calculated for all problems, or for problems with a specified number of moves (one move to five or six moves).

Test Modes

OTS has four modes, with varying numbers of problems and boxes.

Cambridge Neuropsychological Test Automated Battery, Fig. 9 Spatial span

Spatial Span (SSP)

See Fig. 9.

Overview

Spatial Span assesses working memory capacity, and is a visuospatial analogue of the Digit Span test.

Administration Time

Around 5 min, depending on level of impairment

Task

White squares are shown, some of which briefly change color in a variable sequence. The participant must then touch the boxes which changed color in the same order that they were displayed by the computer (for clinical mode) or in the reverse order (for reverse mode). The number of boxes increases from two at the start of the test to nine at the end, and the sequence and color are varied through the test.

Outcome Measures

This test has six outcome measures, covering span length (the longest sequence successfully recalled), errors, number of attempts, and latency.

Test Modes

Two modes: clinical mode and reverse mode.

Spatial Working Memory (SWM)

See Fig. 10.

Cambridge Neuropsychological Test Automated Battery, Fig. 10 Spatial working memory

Overview

SWM is a test of the participant's ability to retain spatial information and to manipulate remembered items in working memory. It is a self-ordered task, which also assesses heuristic strategy. This test is a sensitive measure of frontal lobe and "executive" dysfunction. It has been shown in recent studies that impaired performance on SWM emerges as a common factor in prepsychosis.

Administration Time

Around 8 min, depending on level of impairment

Task

The test begins with a number of colored squares (boxes) being shown on the screen. The aim of this test is that, by touching the boxes and using a process of elimination, the participant should find one blue "token" in each of a number of boxes and use them to fill up an empty column on the right hand side of the screen. The number of boxes is gradually increased, until it is necessary to search a total of eight boxes. The color and position of the boxes used are changed from trial to trial to discourage the use of stereotyped search strategies.

Outcome Measures

The 24 outcome measures for SWM include errors (touching boxes that have been found to be empty, and revisiting boxes which have already

been found to contain a token), a measure of strategy, and latency measures.

Test Modes

Clinical mode

Stockings of Cambridge (SOC)

See Fig. 11.

Overview

SOC is a spatial planning test which gives a measure of frontal lobe function

Administration Time

Around 10 min, depending on level of impairment.

Task

The participant is shown two displays containing three coloured balls. The displays are presented in such a way that they can easily be perceived as stacks of coloured balls held in stockings or socks suspended from a beam. This arrangement makes the 3-D concepts involved apparent to the participant, and fits with the verbal instructions.

The participant must use the balls in the lower display to copy the pattern shown in the upper display. The balls may be moved one at a time by touching the required ball, then touching the position to which it should be moved. The time taken to complete the pattern and the number of moves

required are taken as measures of the participant's planning ability.

Outcome Measures

This test has three outcome measures, including the number and percentage of correct trials and latency (speed of participant's response).

Test Modes

Clinical mode

CANTAB Attention Tests

These tests measure different aspects of attention and reaction time. *Choice Reaction Time (CRT)*, *Rapid Visual Information Processing (RVP)*, and *Simple Reaction Time (SRT)* use the press pad exclusively as an input device; *Match to Sample Visual Search (MTS)* and *Reaction Time (RTI)* use both the press pad and the touch screen.

Choice Reaction Time

See Fig. 12.

Overview

Choice Reaction Time (CRT) is a two-choice Reaction Time test which is similar to the *Simple Reaction Time (SRT)* test, except that stimulus and response uncertainty are introduced by having two possible stimuli and two possible responses.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 11 Stockings of Cambridge

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 12 Choice reaction time

It is useful for testing general alertness and motor speed.

Administration Time

Around 7 min, depending on level of impairment

Task

An arrow-shaped stimulus is displayed on either the left or the right side of the screen.

The participant must press the left hand button on the press pad if the stimulus is displayed on the left hand side of the screen, and the right hand button on the press pad if the stimulus is displayed on the right hand side of the screen.

Outcome Measures

This test has 13 outcome measures, assessing correct and incorrect responses, errors of commission and omission (late and early responses), and latency (response speed).

Test Modes

Clinical mode

Match to Sample Visual Search (MTS)

See Fig. 13.

Overview

Match to Sample Visual Search (MTS) is a matching test, with a speed/accuracy trade-off. It is a simultaneous visual search task with response

latency dissociated from movement time. Efficient performance on this task requires the ability to search among the targets and ignore the distractor patterns which have elements in common with the target. This test can help to differentiate between Parkinson's disease and Alzheimer's disease, and also between Lewy Body dementia and Alzheimer's disease.

Administration Time

Around 9 min, depending on level of impairment

Task

The participant is shown a complex visual pattern (the sample) in the middle of the screen, and then, after a brief delay, a varying number of similar patterns are shown in a circle of boxes around the edge of the screen. Only one of these boxes matches the pattern in the center of the screen, and the participant must indicate which it is by touching it. Reaction time is measured on the basis of the release of the press pad, which allows for its more accurate measurement.

Outcome Measures

The 12 outcome measures for SOC cover the number of problems solved with minimum moves, the mean number of moves for n-move problems, mean initial thinking time for n-move problems, and mean subsequent thinking time for n-move problems.

Test Modes

Clinical mode

Rapid Visual Information Processing (RVP)

See Fig. 14.

Overview

Rapid Visual Information Processing (RVP) is a test of sustained attention (similar to the Continuous Performance Task) and has proved useful in many studies in which drugs are used to help develop a disease model. It is sensitive to dysfunction in the parietal and frontal lobe areas of the brain and is also a sensitive measure of general performance.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 13 Match to sample visual search

Cambridge Neuropsychological Test Automated Battery, Fig. 14 Rapid visual information processing

Administration Time
Around 7 min

Task

A white box appears in the center of the computer screen, inside which digits, from 2 to 9, appear in a pseudo-random order, at the rate of 100 digits per minute. Participants are requested to detect target sequences of digits (e.g., 2–4–6, 3–5–7, 4–6–8) and to register responses using the press pad.

Outcome Measures

The nine RVP outcome measures cover latency, probabilities, and sensitivity (calculated using Signal Detection Theory), and hits, misses, false alarms, and rejections.

Test Modes

Clinical mode, plus 123 mode (for children aged 4–8) and 357 mode (for children aged 7–14)

Reaction Time (RTI)

See Fig. 15.

Overview

Reaction Time (RTI) is a latency task with a comparative history (the five choice task) and uses a procedure to separate response latency from movement time. It is more useful than CRT or SRT where it is necessary to control for tremor.

Cambridge Neuropsychological Test Automated Battery, Fig. 15 Reaction time

Administration Time

Around 5 min, depending on level of impairment

Task

The task is divided into five stages, which require increasingly complex chains of responses. In each case, the subject must react as soon as a yellow dot appears. In some stages, the dot may appear in one of five locations, and the subject must sometimes respond by using the press pad, sometimes by touching the screen, and sometimes both.

Outcome Measures

The four outcome measures in RTI are divided into Reaction Time (simple and five-choice) and movement time (simple and five-choice)

Test Modes

Clinical mode, parallel mode, and child mode

Simple Reaction Time (SRT)

See Fig. 16.

Overview

Simple Reaction Time (SRT) is a test which measures simple Reaction Time through delivery of a known stimulus to a known location to elicit a known response. The only uncertainty is with regard to when the stimulus will occur, by having a variable interval between the trial response and the onset of the stimulus for the next trial. Like

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 16 Simple reaction time

Choice Reaction Time (CRT), it is useful for testing general alertness and motor speed, and is often sensitive to medication effects.

Administration Time

Around 6 min, depending on level of impairment

Task

As soon as the participant sees the square on the screen, they must press the button on the press pad.

Outcome Measures

The 11 outcome measures for SRT cover latency (response speed), correct responses, and errors of commission and omission.

Test Modes

Clinical mode

CANTAB – Semantic/Verbal Memory Tests

These tests, which address semantic and/or verbal memory, are relatively new additions to the CANTAB battery consisting of: Graded Naming Test (GNT) and Verbal Recognition Memory (VRM).

Graded Naming Test (GNT)

See Fig. 17.

Cambridge Neuropsychological Test Automated Battery, Fig. 17 Graded naming test

Overview

The Graded Naming Test has been used extensively in cognitive neuropsychology. The Graded Naming Test (GNT) avoids the problem of ceiling effects in previous naming tests by having participants name drawings of objects in ascending difficulty. Reduced efficiency in retrieving the name of an object can be the first and only indication of impaired language functioning. This test assesses object-naming ability, but is in addition graded in difficulty to allow for individual differences. This means that it may be able to detect any word-finding difficulty even in those with an extensive naming vocabulary.

Administration Time

Around 10 min, depending on level of impairment

Task

Thirty different line drawings are displayed on the screen, 1 at a time. The participant must identify the object depicted in each drawing.

Outcome Measures

This test has six outcome measures, which include total correct, total errors, and normative z-score and percentile.

Notes

Currently available in UK English only (this test is culturally biased and there are no alternative versions at present). A pencil and paper version of this test is also available.

Test Modes

Clinical mode

Verbal Recognition Memory (VRM)

See Fig. 18.

Overview

Despite the general desirability of nonverbal tests because of their culture free applicability, researchers and clinical studies sometimes require verbal tests, perhaps because of need to explore questions relating to language or left hemisphere function. Other verbal tests have a long history of use in psychiatric assessment and clinical studies. The Verbal Recognition Memory test, which assesses immediate and delayed memory of verbal information under free recall and forced choice recognition conditions, should provide comparable results.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 18 Verbal recognition memory

Task

In the VRM test, the participant is shown a list of 12 words, 1 at a time, and then asked to:

- Produce as many of the words as possible immediately following the presentation
- Recognize the words they have seen before from a list of 24 words containing the original 12 words and 12 distractors
- Following a delay of 20 min, recognize the words they have seen before from another list of 24 words containing the original list and 12 new distractors

Outcome Measures

The five outcome measures for VRM cover correct and incorrect responses for the recognition and free recall parts of the test.

Notes

Currently available in UK English only

Test Modes

Clinical mode and four parallel modes for repeated testing. Each mode has immediate and delayed parts.

CANTAB – Decision Making and Response Control Tests

These tests add another dimension to cognitive profiling and investigation of frontal lobe function. Most decisions in life have an emotional or risk-related component, and many clinical conditions are associated with inappropriate risk models/strategies.

They consist of Affective Go/No-go (AGN), Information Sampling Task (IST), Cambridge Gambling Task (CGT) and Stop Signal Task (SST).

Affective Go/No-go (AGN)

See Fig. 19.

Overview

This test assesses information processing biases for positive and negative stimuli.

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 19 Affective Go/No-Go

Affective cognitive functions are thought to be related to the ventral and medial-prefrontal cortex areas of the brain because of the limbic connections with this region. As such, the Affective Go/No-go test represents a powerful research assessment tool for current studies on the neural substrates of depression, bipolar disorder, Post-Traumatic Stress Disorder (PTSD), and many other affective conditions.

Administration Time

Around 10 min, depending on level of impairment

Task

The test consists of several blocks, each of which presents a series of words from two of three different affective categories: Positive (e.g., joyful), Negative (e.g., hopeless), and Neutral (e.g., element). The participant is given a target category, and is asked to press the press pad when they see a word matching this category.

Outcome Measures

Twelve outcome measures covering latency and errors of commission and omission

Note

Currently available in English only.

Test Modes

Six modes, four using positive and negative stimuli only, and two using positive, negative, and neutral stimuli

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 20 Cambridge gambling task

Cambridge Gambling Task (CGT)

See Fig. 20.

Overview

The Cambridge Gambling Task was developed to assess decision making and risk-taking behavior outside a learning context. Relevant information is presented to the participants “up-front” and there is no need to learn or retrieve information over consecutive trials.

Unlike other “Gambling” tasks, CGT dissociates risk taking from impulsivity, because in the ascending bet condition, the participant who wants to make a risky bet has to wait patiently for it to appear. The likely neural substrate for this task is the orbitofrontal prefrontal cortex. Traumatic Brain Injury, Alcoholism, and Drug abuse are all conditions sensitive to this test.

Administration Time

Up to 30 min

Task

On each trial, the participant is presented with a row of ten boxes across the top of the screen, some of which are red and some of which are blue. At the bottom of the screen are rectangles containing the words “Red” and “Blue.” The participant must guess whether a yellow token is hidden in a red box or a blue box.

In the gambling stages, participants start with a number of points, displayed on the screen, and can select a proportion of these points, displayed in

either rising or falling order, in a second box on the screen, to gamble on their confidence in this judgment. A stake box on the screen displays the current amount of the bet. The participant must try to accumulate as many points as possible.

Outcome Measures

The six CGT outcome measures cover risk taking, quality of decision making, deliberation time, risk adjustment, delay aversion, and overall proportion bet.

Test Modes

Ascending first (where stakes are displayed in ascending order for two stages, then in descending order for two stages) and Descending first (where stakes are displayed in descending order for two stages, then in ascending order for two stages).

Information Sampling Task (IST)

See Fig. 21.

Overview

The Information Sampling Task (IST) tests impulsivity and decision making.

Administration Time

Up to 15 min

Task

The subject is presented with a 5×5 array of gray boxes on the screen, and two larger colored panels

below these boxes. The subject is instructed that they are playing a game for points, which they can win by making a correct decision about which color is in the majority under the gray boxes. They must touch the gray boxes one at a time, which open up to reveal one of the two colors shown at the bottom of the screen. Once a box has been touched, it remains open. When the subject has made their decision about which color is in the majority, they must touch the panel of that color at the bottom of the screen to indicate their choice. After the subject has indicated their choice, all the remaining gray boxes on the screen reveal their colors and a message is displayed to inform the subject whether or not they were correct. The colors change from trial to trial.

There are two conditions – the fixed win condition, in which the subject is awarded 100 points for a correct decision regardless of the number of boxes opened, and the decreasing win condition, in which the number of points that can be won for a correct decision starts at 250 and decreases by 10 points for every box touched. In either condition, an incorrect decision costs 100 points.

Outcome Measures

The eight IST outcome measures cover errors, latency, total correct trials, mean number of boxes opened per trial, and probability of the subject's decision being correct based on the available evidence at the time of the decision.

Test Modes

IST has two modes:

- Fixed win-decreasing win (after practice trials, the fixed win stage precedes the decreasing win stage)
- Decreasing win-fixed win (after practice trials, the decreasing win stage precedes the fixed win stage)

Stop Signal Task (SST)

See Fig. 22.

Overview

SST is a classic stop signal response inhibition test, which uses staircase functions to generate an estimate of stop signal reaction time.

©2011 Cambridge Cognition - All rights reserved

©2011 Cambridge Cognition - All rights reserved

Cambridge Neuropsychological Test Automated Battery, Fig. 22 Stop signal task

This test gives a measure of an individual's ability to inhibit a prepotent response.

Administration Time

Up to 20 min

Task

This test consists of two parts.

In the first part, the participant is introduced to the press pad, and told to press the left hand button when they see a left-pointing arrow, and the right hand button when they see a right-pointing arrow. There is 1 block of 16 trials for the participant to practice this.

In the second part, the participant is told to continue pressing the buttons on the press pad when they see the arrows, as before, but, if they hear an auditory signal (a beep), they should withhold their response and not press the button.

Outcome Measures

SST has five outcome measures, each of which can have various options applied to it. The SST measures cover direction errors, proportion of successful stops, RT on GO trials, SSD (50%), SSRT.

Test Modes

SST has one mode: clinical.

Social Cognition

A range of disorders are known to affect social cognition and there is an expanding research field

examining how such conditions may bias cognitive processes involved in social interaction. This domain is assessed by: Emotion Recognition Task (ERT).

Emotion Recognition Task (ERT)

Overview

ERT measures the ability to identify emotions in facial expressions. The participant is shown a series of faces which appear on the screen briefly and asked to identify the emotion (happiness, sadness, anger, disgust, surprise and fear).

Administration Time

Around 10 min, depending on level of impairment.

Task

One hundred and eighty stimuli, which are computer morphed images derived from the facial features of real individuals each showing a specific emotion, are displayed on the screen, one at a time, in two blocks of ninety. Each face is displayed for a short while (200 ms) and then immediately covered up, and then six buttons are displayed, each describing an emotion which could be portrayed in the photograph. The participant must decide which is the appropriate button to describe the emotion and touch the button. There are fifteen different photographs for each of the six emotions, each showing different levels of intensity.

Outcome Measures

The outcome measures for ERT cover percentages and numbers correct or incorrect, and overall response latencies. Results can be looked at across individual emotions, or across all emotions at once.

Test Modes

ERT is available for clinical trials immediately, and will be available for academic research in CANTABeclipse 5. Please contact Cambridge Cognition for further information.

ERT takes around 10 min to administer in healthy individuals.

Other Tests

Visual Analogue Scales (VAS)

Overview

Visual Analogue Scales are psychometric response scales which can be used as a measurement instrument for subjective states. The CANTAB VAS assess subjective measurements of drug effect, energy levels, sickness, alertness and mood.

Administration Time

Around 5 min, depending on level of impairment.

Task

The participant must respond to sixteen questions as they appear on the screen by touching the on-screen slider and moving it to the appropriate position on the scale.

Outcome Measures

The outcome measures for this test allow you to look at the data on a question-by-question basis.

Test Modes

Please contact Cambridge Cognition for information about availability for academic research.

Historical Background

Grounded in the neurosciences, the CANTAB[®] neuropsychological tests were developed more than 21 years ago at the University of Cambridge by Professors Robbins and Sahakian, to enable detailed translational assessment and evaluation of cognitive function. Lesion, neuroimaging, clinical and psychopharmacological studies have enabled a unique understanding of the structural, clinical and biochemical sensitivities of each of the tests. (CANTAB)

The CANTAB battery was developed for the assessment of cognitive deficits in humans with neurodegenerative diseases or brain damage (Fray and Robbins 1999). It consists of a series of inter-related computerized tests of memory, attention, and executive function, administered via a touch-sensitive screen. It allows a decomposition of

complex tasks commonly used in clinical assessment into their cognitive components and enables the extrapolation of findings from the animal literature. Tests include versions of the Wisconsin Card Sorting Test and the Tower of London and also the Delayed Matching to Sample test, widely used in monkeys for visual recognition memory. The tests are constructed in such a way that they may be given to animals (monkeys) with minimal change. The nonverbal nature of the CANTAB tests makes them largely language independent and culture free. CANTAB has been standardized on a large, predominantly elderly, population and validated in neurosurgical patients as well as in patients with basal ganglia disorders, Alzheimer's disease, depression, and schizophrenia. In addition, CANTAB has been used to evaluate: (a) the therapeutic effects of dopaminergic and cholinergic medication in neurodegenerative disease; (b) cognition in 5–11-year old normal, learning-disabled, and autistic children; (c) deficits in patients with HIV infection; and (d) early, asymptomatic Huntington's disease. The latter illustrate its usefulness in early identification of progressive disorders. It is suggested that the battery should have particular utility across a wide range of age and intelligence in longitudinal assessment after exposure to toxicants, and allow meaningful comparison with experimental studies of toxic effects in other species.

There is emerging evidence to support the involvement of frontal cortex in autism. CANTAB is particularly useful in helping study the cognitive profile of children who have autism and related disorders.

Psychometric Data

CANTAB tests are sensitive to cognitive changes caused by a wide range of CNS disorders and medication effects.

Where error scores are a key outcome measure, CANTAB tests are graded in difficulty to avoid ceiling effects.

Where accurate measurement of latency is important, responses are made via a press pad. Elsewhere, engaging touch-screen technology maximizes compliance.

The majority of CANTAB tests are independent of language and culture.

Clinical Uses

The following cognitive and other disorders have been investigated using CANTAB®:

AD/HD – Attention deficit hyperactivity disorder	Lesion in orbitofrontal cortex
AIDS dementia complex	Liver failure
Alcoholism	Long-term health effects of diving
Amphetamine addiction	Machado-Joseph disease
Amygdalo-hippocampectomy	Mad Hatter's disease
Anorexia nervosa	Manic depression
Anterior parietal damage	Melancholia
Antisocial behavior	Mercury poisoning
Antisocial personality disorder	Mild cognitive impairment (MCI)
Anxiety	Motor neuron disease
Attention deficit-hyperkinetic disorder	Multiple sclerosis
Autism	Multiple system atrophy
Basal ganglia lesions	Narcolepsy
Bipolar disorder	Neuronal migration disorders
Borderline personality disorder	Normal pressure hydrocephalus
Camptocormia	Obsessive compulsive disorder
Capgras syndrome	Organophosphate pesticide exposure
Carcinoid syndrome	Panic disorder
Chronic drug misuse	Paraphrenia
Chronic fatigue syndrome	Parkinson's disease
Chronic occupational solvent encephalopathy	Periventricular brain insult
Critical illness requiring intensive care	Personality disorder
Dementia Alzheimer-type (DAT)	Petrol (gasoline) sniffing
Dementia lewy body type	Phenylketonuria
Dementia of frontal type	Post-concussion syndrome
Developmental dyslexia	Premature birth needing intensive care

(continued)

Diabetes	Premenstrual dysphoric disorder
Dorsolateral frontal cortical compression	Progressive supranuclear palsy
Down's syndrome	Psychopathy
Drug abuse	Psychosis
Dysexecutive syndrome	Questionable Dementia
Frontal lobe damage	Renal Cancer
Frontal lobe excision	Roifman syndrome
Frontal variant frontotemporal dementia	Schizoaffective disorder
Gluten ataxia	Schizophrenia
Hallucinosis	Seasonal affective disorder
Head injury	Self harm
Hearing loss	Semantic dementia
Heart disease	Specific language impairment
Heart failure	Social withdrawal in Schizophrenia
Heavy social drinking	Solvent encephalopathy
Hepatic encephalopathy	Spina bifida
Heroin addiction	Steele-Richardson-Olzewski syndrome
Herpes encephalitis	Stiff Person syndrome
Hippocampal atrophy	Striatocapsular infarct
HIV/AIDS	Subarachnoid hemorrhage
Huntington's disease	Substance abuse
Hydrocephalus	Tardive dyskinesia
Hypercortisolemia	Temporal lobe excision
Hyperostosis frontalis interna	Temporal lobe lesion
Hypertension	Tinnitus
Insomnia	Tourette's syndrome
Korsakoff syndrome	Traumatic brain injury
Late paraphrenia	Trichotillomania
Lead exposure	Tuberous sclerosis
Left ventricular systolic dysfunction	White matter lesions

Drugs

Pharmacological studies (academic research) have been carried out on the following drugs using CANTAB:

Alcohol	Flumazenil	Modafinil
Amisulphiride	Fluoxetine	Neuroleptic
Amphetamine	Galantamine	Nicotine

(continued)

Antipsychotic medication	<i>Ginkgo biloba</i>	Olanzapine
Antiretroviral therapy	Glyburide	Opiates
Atomoxetine	Guanfacine	Paroxetine
Branch chain amino acid drink	Highly active antiretroviral therapy (HAART)	Pergolide
Bromocryptine	Haloperidol	Perindopril
Buspirone	Heroin	Petrol/ Gasoline
Caffeine	Hydrocortisone	Phenserine
Cannabis	Idazoxan	Quetiapine
Chlorpromazine	Idazoxan plus Clonidine	Risperidone
Clonidine	Interferon	Ritalin
Clozapine	Interleukin-2	Rivastigmine
Cocaine	Kava	Rosiglitazone
delta-9 tetrahydrocannabinol	Ketamine	RU-486
Dexamphetamine	L-Dopa	Scopolamine
Diazepam	Lecithin	SGS742
Donepezil	MDMA	Sulpiride
Dopaminergic medication	Metamphetamine	Tacrine
Ecstasy	Methylphenidate	Tryptophan
Endozepines	Mifepristone	Tyrosine

Camouflaging Autistic Traits Questionnaire (CAT-Q)

Laura Hull and William Mandy
Research Department of Clinical, Educational and Health Psychology, University College London, London, UK

Synonyms

[CAT-Q](#)

Description

The Camouflaging Autistic Traits Questionnaire (CAT-Q) is a standardized self-report measure of camouflaging behaviors in autistic and non-autistic adults. It comprises 25 items and takes around 5 min to complete, on paper or online. The scale consists of three sub-scales: compensation (strategies used to overcome social difficulties associated with autism), masking (strategies used to hide autistic characteristics or present a less autistic persona), and assimilation (strategies used to avoid standing out during social interactions). In addition to sub-scale scores, a total camouflaging score can be calculated as the sum of all scores (ranging from 25 to 175, with higher scores indicating greater camouflaging). The CAT-Q is completed by the individual themselves, reflecting on their own behaviors at the present time.

Historical Background

Camouflaging describes the use of strategies, whether deliberate or automatic, to minimize the appearance of autistic characteristics during social interactions and to compensate for social difficulties associated with autism (Hull et al. 2017). Camouflaging has also been proposed as a potential explanation for the underdiagnosis of autism in females (Lai et al. 2015); if girls and

women use more, or more successful, camouflaging strategies to hide or compensate for their autism, they are less likely to be identified by clinical services. This can lead to lack of support and acceptance, as well as the potential for resulting mental health difficulties (Bargiela et al. 2016; Milner et al., 2019). Recent research has also suggested that camouflaging strategies themselves may be associated with negative mental health outcomes for autistic adults (Cage et al. 2018; Hull et al. 2017) and young people (Tierney et al. 2016).

Until recently there has been no way to measure how much someone is camouflaging. Some researchers have quantified camouflaging as the discrepancy between an individual's internal autistic experience (such as level of autistic traits) and the external behavioral presentation (such as ADOS score; Lai et al. 2017). This approach has generally concluded that females camouflage more than males (Lai et al. 2017, 2018; Parish-Morris et al. 2017; Ratto et al. 2018).

However, the discrepancy approach to measuring camouflaging requires multiple, often time-consuming measures to be taken for each individual and only measures the effect camouflaging has on behavior rather than the effort put into camouflaging. An alternative measurement is the CAT-Q, which directly measures the extent of camouflaging strategies self-reported by an individual. This makes measurement of camouflaging quick and easy, and the CAT-Q is freely available to download (Hull et al. 2018).

Psychometric Data

There is limited psychometric data for this measure, particularly across cultures, abilities, and age groups. The CAT-Q has been validated in autistic and non-autistic adult males and females in a large sample ($N = 832$; Hull et al. 2018) and demonstrated good internal consistency ($\alpha = 0.94$ for total camouflaging scale) and acceptable test-retest reliability in a smaller

sample ($ICC [C,1] = 0.77$). Measurement invariance has also been demonstrated between autistic and non-autistic males and females, demonstrating that the CAT-Q can be used with individuals regardless of whether they have received a formal diagnosis of autism. This is particularly important as camouflaging is likely to exist along a continuum, similarly to autistic traits (Constantino, 2011), and individuals who camouflage extensively may consequently not meet current diagnostic criteria for autism (Kreiser and White 2014). There is some evidence to support the convergent validity of the CAT-Q, with higher scores associated with higher levels of autistic-like traits (Hull et al. 2018).

Clinical Uses

Camouflaging has been associated with mental health difficulties including depression (Lai et al. 2017), anxiety (Hull et al. 2018), and suicidal thoughts (Cassidy et al. 2018). The CAT-Q can be used to identify autistic adults who may be a greater risk of these co-occurring conditions and help them access support. However, norms have not yet been established for either autistic or non-autistic adults; therefore clinically meaningful cutoffs have not been identified.

There is also potential for the CAT-Q to be used as part of the autism diagnostic assessment process in adults and adolescents. Adults, particularly women, who have not yet received an autism diagnosis, may camouflage their characteristics during autism assessments, leading to under-recognition of their level of need. Further clinical research is needed to examine exactly how the CAT-Q can be integrated into gold standard assessment processes.

Can't Versus Won't Dilemma

Elaine Coonrod

Department of Psychiatry, School of Medicine, TEACCH, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

One common issue faced by parents, teachers, and caregivers of individuals with autism is understanding when a behavioral difficulty is due to a skill deficit (“can’t”), rather than due to deliberate noncompliance (“won’t”). Caregivers who attribute behavior problems to deliberate noncompliance often see the behavior as rooted in laziness, stubbornness, or defiance. This attribution has multiple negative consequences, including increased frustration and stress for the caregiver, as well as use of ineffective or confrontational behavior management strategies.

Even caregivers who have some understanding of autism may believe that the individual with autism is purposely engaging in misbehavior, and consequently become embroiled in an unproductive power struggle. The confusing behavioral picture presented by individuals with autism contributes to this misunderstanding. For example, individuals with autism often have a very typical physical appearance, so the caregivers’ natural inclination is to expect age-appropriate skills and behavior. In addition, many individuals with autism, including those with language impairments, can repeat back

verbal directions even when they have not fully understood the content of what was said, giving a misimpression about their level of understanding. Furthermore, poor social insight and communication deficits may mean that individuals with autism are unable to recognize and communicate their own lack of skill or need for assistance, or may cause them to question directions from others in a manner that is perceived as argumentative or disrespectful. Perhaps most confusing for caregivers is the unusual scatter of strengths and weaknesses shown by individuals with autism, as well as their difficulty in generalizing the use of skills from one context to another. For example, parents of a bright 14 year old with autism may simply have difficulty understanding how their son can have extensive working knowledge of his computer, yet not be able to successfully operate the microwave. A teacher of a more impaired 7 year old may be confused as to why the student can independently use the toilet at home but repeatedly soils her clothing at school.

In general, when faced with a “can’t versus won’t” dilemma, it is more productive to begin by assuming that the individual with autism “can’t” and then conduct a behavioral assessment focused on the symptoms of autism that may be impeding his or her behavioral success. The caregiver should consider the ways in which the individual’s unique profile of strengths and weaknesses in communication, socialization, flexibility and interests, sensory responses, and learning style may be contributing to the behavioral difficulty. That information can then be used to generate positive, proactive strategies to help support desired behaviors in the future.

Background

In Canada, as in many other countries, a growing public awareness of autism spectrum disorder (ASD) has emerged in the context of the evidence for a rising prevalence and the existence of life-long vulnerabilities and complex medical and mental health comorbidities (Anagnostou et al. 2014). Parents and carers have been instrumental in raising this awareness, and the government has responded with the commissioning of new services, principally focused on the needs of children (Motiwala et al. 2006; Auditor General of Ontario 2013). As discussed subsequently, despite increased public funding for ASD-focused services, significant inequalities in service provision exist for specific groups, including adults and higher-functioning individuals (Shattuck et al. 2012), newly arrived immigrants (Khanlou et al. 2017), and individuals with complex health and social care needs (Autism Ontario 2008). Moreover, service inequalities exist between different provinces (Eggleton and Keon 2007). It is now widely recognized that there is an urgent need for uniformly accessible services for all individuals with ASD, irrespective of age or any other characteristic. The provision of a uniform service can only truly be achieved through federal

involvement and ultimately a national policy or legislative framework. Such a strategy has widespread support and in 2007 was a suggestion made by the Senate Select Committee (Eggleton and Keon 2007), although at this stage there is no indication of the adoption of a federal initiative.

By way of background, in Canada, each province (of which there are ten, along with three territories) is responsible for providing healthcare and social services for all individuals. This of course includes children and adults with developmental disabilities, such as ASD. Funds for services are raised through taxation, and each province implements its own model of service delivery. Importantly, for healthcare federal policy – by way of the Canada Health Act – still provides some oversight and direction, including the directive that universal access to publically funded “medically necessary” services must be ensured for all. However, the significant power devolved by the government to provincial policymakers does result in interprovincial variation in services. It is difficult to articulate the minutiae of province-by-province differences, and so this present entry will provide a simple overview, drawing examples from individual provinces but not attempting to present a detailed and comprehensive picture of ASD services across Canada.

Overview of Current Treatments and Centers

Early Diagnosis and Intervention

One significant development across Canada has been the widespread availability of early intervention services for children with ASD (Anagnostou et al. 2014; Volden et al. 2015). Early intervention, based on the principles of Applied Behavior Analysis (ABA), is funded at the provincial level by those Ministries responsible for child, family, and community care. For example, in Ontario such services are commissioned by the Ministry of Child and Youth Services (separate from the Ministry of Health which is responsible for healthcare), in Alberta by the Ministry of Children’s Services, and in British Columbia (BC) by

the Ministry of Children and Family Development. Early intervention programs (Intensive Behavioural Intervention or IBI) involve one-on-one therapy during which the child is engaged in a series of discrete trials involving reward contingencies to facilitate learning and generalization. The trials themselves focus on language and communication, as well as social and adaptive skills. Intensive intervention typically involves 20–40 h of 1:1 therapy per week over a period of 2 years, which has been shown to maximize the chance of improvement (Reitzel et al. 2015 and references therein).

Research has consistently shown that early language and cognition are strong predictors of outcome in later childhood and into adulthood (Henninger and Taylor 2013), although outcome in later adult life may be related more closely to early social adjustment (Howlin et al. 2013). The increased availability of early intervention services has therefore been welcomed by all involved in ASD policy. Moreover, research has shown the success of such programs (Warren et al. 2011), although the research is not clear cut (Reichow et al. 2012). There is still much interprovincial variation in service delivery: for example, in Nova Scotia publicly funded IBI services are available to all young children with ASD, and this level of care is echoed in Ontario. As would be expected, with the evidence for a rising prevalence, currently estimated at ~1% (or 67,000 children age between 3 and 20 years) in Canada (Anagnostou et al. 2014), the demand on these services is large, and consequently wait times are often long between receiving a diagnosis and accessing IBI. Some form of triage is often in place to target those children who are more likely to benefit. For example, in Ontario IBI is reserved for younger children who have “severe autism.” Although “severe” is not explicitly defined, clinicians responsible for intake use a variety of screening tools to determine eligibility. However, even targeting services in this way, wait times are still substantial. For example, in 2013, the waitlist for IBI in Southern Ontario, comprising parts of the Greater Toronto Area (GTA) and the surrounding “Golden Triangle,” included 1748 children (Auditor General of Ontario 2013). Slightly

different service provision is seen in BC and Alberta, where public funding is provided to partly offset the costs of private intervention sourced by the family itself.

Early intervention demands that diagnosis is made as early as possible, which is dependent on the availability of expert clinical diagnostic services. Although certain groups, such as the American Academy of Pediatrics, have recommended universal screening for ASD between the ages of 18 and 24 months (Johnson and Myers 2007), the Canadian Pediatric Society instead advises developmental surveillance (Anagnostou et al. 2014). In parts of Canada, this approach has been facilitated through the use of brief, validated, and reliable screening questionnaires (Zwaigenbaum 2009). While family physicians are in a position to provide early screening, however, the diagnosis itself may be delayed through the unavailability of appropriate expertise. While family physicians are the frontline staff involved in developmental surveillance, the responsibility for early diagnosis rests with existing services, such as developmental pediatrics and child psychiatry. The provision of adequate training to primary and secondary healthcare workers is therefore crucial.

School-Aged Children

Services for school-aged children have also seen progress in recent years. In some provinces, the focus remains on early intervention for pre-schoolers, whereas other provinces have also developed services for children with ASD up to the age of 18 years. In Ontario, for example, services have developed to meet the varying needs of this population using ABA principles. Among some children with ASD, particularly those who function typically, the focus may be on social skills, often, although not necessarily, delivered in a group setting, whereas for others, it may be behavioral or adaptive needs. The emphasis is on mastering skills one at a time and then learning to apply these in everyday settings. In 2013, the median age of children accessing this service was 8 years, with 90% age 14 or younger indicating that older children and those in

transition (i.e., age 17–18 years) may not be accessing services. In addition to therapy that targets the core symptoms of ASD, there is also a need for mental health services to address the high level of emotional distress and comorbidity among children with ASD (Drmic and Szatmari 2014). The impact on later outcome for therapy aimed at school-aged children will need to be fully evaluated.

Adults

Services for adults with ASD in Canada have lagged behind those for children (Stoddart et al. 2013). It is estimated that in the region of 4900, teenagers with ASD in Canada reach their 18th birthday each year (Shattuck et al. 2012). Based on current epidemiological estimates, as many as 70% of these may have IQs in the typical range (Centers for Disease Control and Prevention 2014). Despite this, however, the outcome for many is poor. For example, studies of outcomes consistently find low to modest levels of independence and the persistence of core phenotypic traits and associated developmental and mental health vulnerabilities beyond childhood (Howlin et al. 2013). It is clear, therefore, that for an individual with ASD – irrespective of their IQ – health and community/social care needs will remain significant throughout much of their lives (Stoddart et al. 2013; Autism Ontario 2008). With increases in life expectancy, this potentially represents a public health crisis. Indeed, on an individual basis, the lifetime costs associated with ASD have been estimated at up to \$2.44M US dollars in the USA and UK (Buescher et al. 2014).

Healthcare for adults with ASD in Canada is met according to the universal healthcare principles of the Canada Health Act. Specialist mental health services for adults with developmental disabilities do exist but are not government mandated. Such services focus on the mental health and behavioral needs of adults with IQs below 70, and as such, many adults with ASD will not meet the access criteria. For those adults who do have IQs 70 or above, it is expected that existing mental health services will meet their needs, although this is often not the case, with some excluded from community mental health services

as a result of their ASD diagnosis, essentially leaving them “doubly socially excluded.” This is even more concerning when the statistics are considered: in one study examining comorbidity, as many as 70% of young adults with ASD had experienced one or more episode of major depression, with 50% experiencing recurrent depression and 50% describing an anxiety disorder (Lake et al. 2014).

In Canada, vocational and social care needs, including the provision of supported accommodation, are met by the Ministry responsible for the commission of community and social services. Among those who have an intellectual disability, i.e., evidence of IQ <70 along with adaptive impairments, a variety of services are available, although the large demand for services results in long wait times. Such services include supported living and respite, supported employment and other vocationally centered programs, and behavioral services. Adults with ASD who have IQs above 70, however, are generally denied access to such services (Stoddart et al. 2013; Autism Ontario 2008). As such, the emphasis has been on private initiatives. For example, in Alberta the Sinneave Foundation in collaboration with the consulting firm Meticulon provides individuals with autism an opportunity to work with the IT field while providing them with the appropriate wages. The availability of similar initiatives exist across the country.

Specific Issues

Rural communities have identified a definite lack of resources and services when tending to the needs of their children. The lack of medical support has made life difficult for families and providing proper treatment difficult as there are no professionals or workers to provide the training and insight to how to provide the best environment for their children to grow (Hoogsteen and Woodgate 2013). Similar barriers to service access is seen among newly arrived immigrants to Canada (Khanlou et al. 2017). Rates of ASD have been shown to be 36% higher in children of immigrant mothers. Considering the fact that migration is an integral part of Canadian federal policy and that a significant proportion of

Canada’s population is made up of newly arrived immigrants, this represents a major area of need. Addressing this requires a better understanding of the barriers to care, which will include, for example, language and knowledge of existing structures, as well as federal policy to overcome these barriers.

Other specific issues relate to the organization of existing structures of care. For example, transition planning and implementation continues to present a major challenge for families, with the negotiation of adult services an extra hurdle at an already difficult time (Gorter et al. 2011). Hospitals themselves are often not set up to manage individuals with ASD and other developmental disabilities effectively. For example, it has been argued that emergency departments are poorly equipped to accommodate patients with ASD appropriately (Nicholas et al. 2016). Key problems identified are lack of communication and training. The same concern has been expressed in relation to primary care, although initiatives such as the Primary Care Developmental Disabilities Network in Ontario attempts to overcome this barrier through more adequate training (Sullivan et al. 2011).

Overview of Research Directions

Canada has a long tradition of research in ASD, with basic and applied scientific approaches being used to further the knowledgebase on ASD. These comprise a number of multisite, high-impact, studies. By way of example, two research programs are briefly highlighted below.

Pathways

This large, multisite project comprises researchers across five Canadian provinces (Ontario, Quebec, Nova Scotia, Alberta, and British Columbia). It has recruited newly diagnosed children with ASD, aged between 2 and 4 years, and prospectively following these children to examine their developmental trajectories (Szatmari et al. 2015). Across time, data is collected at four separate intervals, with core symptomatology, behavior, and adaptive function all being measured in detail.

This is a powerful design for a number of reasons. Importantly, most previous studies have recruited participants at different points in the natural history of their disorder. Without sampling an inception cohort (a group assembled at a common time point early in the development of the disorder), there is no way of ensuring that all subgroups of children with ASD are included in the sampling frame. Additionally, in many other studies, individuals with ASD are recruited through clinics, which may introduce bias into the outcomes being observed.

Genetics

Canada has a long tradition of genetics research in autism spectrum disorder, utilizing state-of-the-art techniques to attempt to unravel the genetic component of ASD's etiology. In recent years, the focus has been on identifying de novo and inherited unbalanced copy number variation (CNV) (Pinto et al. 2014), including variation at the single nucleotide level (SNV). The current research activities of this multisite, multidisciplinary group focus on the MSSNG project, a collaboration between Google and Autism Speaks under the directorship of Prof. Steve Scherer that aims to sequence the DNA of over 10,000 families with one or more members affected by autism (Yuen et al. 2017).

Current Controversies

The development of services in Canada in recent years has seen a major injection of money, particularly in relation to IBI programs aimed at young children. These programs have been developed along evidence-based lines and are constantly evaluated to make certain of clinical impact. The provincial-led nature of these programs means that there remain inequalities of care across the country as a whole, with rural communities often having the least joined-up level of care. Furthermore, adults, and particularly those who are higher functioning, have seen the least in the way of service development. The need for a federal approach to ASD-specific policy has been raised but not yet adopted.

Candidate Genes in Autism

Youeun Song¹ and Abha R. Gupta²

¹Child Study Center, Yale University School of Medicine, New Haven, CT, USA

²Developmental-Behavioral Pediatrics, Child Study Center, Yale University, New Haven, CT, USA

Definition

Although twin and family studies show that genes play a critical role in determining the risk for autism, its specific genetic etiology remains largely unknown. A candidate gene is one for which there is some evidence of contribution to the etiology of a disorder but for which this has not yet been definitively demonstrated. These genes are identified by a variety of techniques including linkage analysis, association studies, cytogenetic analysis, studies of copy number variation, and next-generation sequencing. Typically, once a candidate gene has been identified, it is reinvestigated via analysis in independent patients' samples. Particularly for studies that rely on case-control comparisons, replication is essential to elevating a candidate gene to a "risk" gene.

Historical Background

Over the past decade, many studies have shown that autism is not a simple Mendelian disorder caused by a single gene at the population level. In the early phase of autism gene discovery, the majority of candidate genes were selected for study based on biological plausibility; that is, they were involved in some biological process that could conceivably play a role in ASD. These genes were then typically evaluated in candidate gene association studies in which one or a small number of common genetic polymorphisms in or near one or a small number of genes were evaluated in cases versus controls. If an overrepresentation of a particular allele or alleles was identified, the gene was considered a candidate ASD gene. These studies were based on the hypothesis that common alleles were responsible for the disorder.

Across all of medicine, the majority of such studies proved difficult to replicate. In retrospect, it is clear that approach had some significant limitations. Among these, the chances of choosing correctly among millions of genetic variations were low, the effect sizes carried by common alleles for most common medical conditions were much smaller than anticipated (resulting in studies that were in retrospect often markedly underpowered), and there were multiple potential confounds, including ancestral mismatching of cases and controls, that were difficult to control for. More recently, the approach has been replaced for the most part by genome-wide association studies, typically of large patient cohorts, that eliminate many of these difficulties. This approach has led to the identification of replicated risk alleles in many common medical conditions, including schizophrenia and bipolar disorder. To date, this approach has led to the identification of several new candidate genes in ASD, but these have not yet replicated in well-powered studies.

Over the last several years, the identification of candidate genes through studies of common variation has been complemented by studies of rare variation. Here again, it is common practice to pursue an initial observation with an attempted independent replication. With rare variations, the

infrequency of individual mutations and the overall genetic heterogeneity of autism may make such studies difficult to mount. A variety of approaches are being developed in an effort to provide a path to confirm candidate loci: these include assessing the total amount of rare variation in a gene in cases versus controls (as opposed to asking questions about one particular rare allele). This approach is often called a mutation burden analysis. In addition, there are ongoing efforts to take advantage of particular types of variation, including *de novo* mutations, to increase the power to detect and confirm the association of a gene or locus with ASD risk (Sanders et al. 2011).

Current Knowledge

Genome-Wide Linkage Studies

Linkage studies identify chromosomal loci inherited by affected individuals more frequently than expected by chance. These studies most often investigate multiplex families in which there is more than one affected person. DNA polymorphisms are used as markers of chromosomal loci throughout the genome. The closer the marker is to a disease gene, the more likely there is cosegregation between the marker and the phenotype under study. The likelihood that a locus is linked to the phenotype is represented as the LOD score (logarithm of the odds). For example, a LOD score of 3 means that there is 1,000 to 1 odds that the locus is linked to the phenotype. When the LOD score is more than 2.2, linkage is considered suggestive; 3.6 is considered significant (Lander and Kruglyak 1995). Linkage peaks have been found on almost every chromosome. As reviewed by Gupta and State (2007), loci with among the highest LOD scores are 3q26.32 (LOD 4.81), 2q31.1 (LOD 4.80), 17q11.2 (LOD 4.3), 17q21.32 (LOD 4.1), and 7q36.1 (LOD 3.7). For the most part, linkage studies in autism have failed to replicate each other, probably due to a number of reasons, such as nonuniform criteria for patient selection, differing sets of polymorphisms, and differing statistical methodologies. A few loci, such as 17q11-q21 and along 7q, have been

highlighted by more than one study (Abrahams and Geschwind 2008). Some of the genes implicated are *CNTNAP2* (contactin-associated protein-like 2), *EN2* (engrailed homeobox 2), *RELN* (reelin), *MET* (MET proto-oncogene), *CADPS2* (Ca²⁺-dependent activator protein for secretion 2), *ITGB3* (integrin beta3), and *SLC6A4* (solute carrier family 6) (Abrahams & Geschwind).

Linkage studies have also been conducted in consanguineous families using homozygosity mapping. Homozygous regions are parts of the genome where the identical chromosomal segment is inherited from both parents due to a recent common ancestor. In homozygosity mapping, it is hypothesized that the disorder is inherited as a recessive trait. Candidate genes found by this method include *DIA1* (deleted in autism-1), *NHE9* (sodium/proton exchanger 9), *PCDH10* (protocadherin 10), and *CNTN3* (contactin 3) (Morrow et al. 2008).

Candidate Gene and Genome-Wide Association Studies

Association studies determine whether there is a statistically significant relationship between exposure to the variant and increased (or decreased) population risk for the phenotype. Numerous genetic association studies have investigated common variants in one or a small number of candidate genes, often selected due to hypothesis-driven disease models. Since these studies are relatively inexpensive, many genes have been evaluated for association with autism, with multiple positive results. However, very few of them have been replicated (Gupta and State 2007). Some genes identified by this method are *GABRB3* (gamma-aminobutyric acid A receptor beta3), *GRIK2* (glutamate receptor ionotropic kainate 2 precursor), *SLC25A12* (solute carrier family 25 member 12), *MET*, *RELN*, *EN2*, *SLC6A4*, and *CNTNAP2* (Abrahams and Geschwind 2008; State 2010). Rare variants can also be investigated by association studies, but this method requires comprehensive resequencing of candidate genes in large cohorts and is expensive. In addition to common variants, rare variants in *CNTNAP2* have been associated with autism (Bakkaloglu et al. 2008).

More recently, high-resolution SNP arrays have enabled genome-wide association studies (GWAS), which query all genes rather than investigating a few candidate genes at a time. Three loci which have been associated with autism are chromosome 5p14.1, between the genes *CDH9* (cadherin 9) and *CDH10* (cadherin 10), chromosome 5p15, near the gene *SEMA5A* (semaphoring 5A), and chromosome 20p12.1, near the gene *MACROD2* (MACRO domain containing 2) (reviewed by State 2010). *CDH9* and *CDH10* are interesting candidate genes since they are involved in neuronal cell adhesion. *SEMA5A* has been implicated in axonal guidance.

Cytogenetic Analysis

Cytogenetic analysis is the study of chromosomal abnormalities such as inversions, translocations, duplications, deletions, and aneuploidies. Traditionally, these abnormalities have been detected via karyotype analysis (microscopic examination of chromosomes). A review by Veenstra-VanderWeele et al. (2004) calculated that 4.3% of the 1826 karyotypes published in the ASD literature are abnormal. Abnormalities have been found on every chromosome, indicating that no one rearrangement is responsible for any substantial fraction of cases. The most common chromosomal abnormality found in ASD is maternally inherited duplications at 15q11-q13 (Abrahams and Geschwind 2008). Some genes which have been implicated by cytogenetic analysis include *NLGN4X* (neuroligin 4X), *UBE3A* (ubiquitin protein ligase E3A), *GABRB3*, *CENTG2* (centaurin gamma 2), *SHANK3* (SH3 and multiple ankyrin repeat domains 3), and *CNTNAP2* (Abrahams & Geschwind; State 2010).

More recently, copy number variations (CNVs) have been investigated using microarrays. Genome-wide CNV analyses have found that CNVs are significantly enriched in neuronal cell adhesion molecules and the ubiquitin pathway (Glessner et al. 2009) and that recurrent de novo copy number variations (CNVs) at 7q11.23, 15q11.2-13.1, 16p11.2, and the *NXRNI* (neurexin 1) locus are strongly associated with autism (Sanders et al. 2011). The 7q11.23 region, the duplication of which is associated with autism in

this study, is previously known to be deleted in Williams-Beuren syndrome, which features a highly social personality, suggesting an intriguing correlation between copy number at this locus and sociability.

Whole-Exome Sequencing

With the development of high-throughput technologies which have been steadily decreasing in cost, it has become possible to obtain the DNA sequence for the entire coding region (exome) of the human genome. This has a profound influence on gene discovery in complex genetic disorders such as ASD. So far, most common variants appear to have small effects on disease risk. Even when large studies have been performed, the vast majority of the genetic contribution to disease risk remains unexplained. These findings suggest that rare variants with relatively large effects may account for a larger fraction of this missing risk than previously anticipated. Whole-exome sequencing enables the identification of rare variants. It can be applied to both large-scale case-control studies and pedigree-based linkage studies.

There are several large whole-exome sequencing studies in progress. Studying simplex families with one affected child, O’Roak et al. (2011) identified de novo mutations in a number of candidate genes: *FOXP1* (forkhead box P1), *GRIN2B* (glutamate receptor, ionotropic, *N*-methyl-D-aspartate 2B), *SCN1A* (sodium channel, voltage-gated, type I, alpha subunit), and *LAMC3* (laminin, gamma3).

Expression Arrays

This method aims at studying alterations in gene expression in autism using postmortem brain tissues or peripheral blood. Some genes implicated include the *EPB41L3* (erythrocyte membrane protein band 4.1-like 3), which interacts with *CNTNAP2*, and the genes relating glutamatergic neurotransmission (Abrahams and Geschwind 2008). Interestingly, genes identified in independent studies share some common pathways such as ubiquitin conjugation, GTPase regulatory activity, and alternative splicing, making them as potential candidates (Abrahams & Geschwind).

Future Directions

Whole-Genome Sequencing: Exome and Regulome

With the rapid development of sequencing technology, whole-genome sequencing has become cost-effective and feasible. The great advantage is the ability to obtain the sequence of regulatory elements (regulome) as well as protein-coding sequence. Regulatory elements regulate the expression of genes and have been understudied in autism. Therefore, whole-genome sequencing has the potential to identify a whole new set of variants which contribute to autism risk.

- Normative data available across age (4–90 years) and IQ levels
- Test-retest reliability data available on many of the tests

The tests that make up the CANTAB are grouped into some of the following general categories (see <http://www.cantab.com/cantab-tests.asp>):

- Screening
- Executive function, planning, and spatial working memory
- Attention and reaction time
- Visual memory and learning
- Decision making and response control
- Semantic/verbal memory
- Social cognition (emotion recognition)

The CANTAB has been used to measure aspects of executive function in individuals with autism including set shifting, planning, and spatial working memory. A brief description of these tasks is as follows (also see <http://www.cantab.com/cantab-tests.asp> for more details):

- Intradimensional/extradimensional (ID/ED) set-shifting task. Assesses the ability to attend to characteristics of simple and compound stimuli, use feedback to learn a rule, and to shift attention within and across dimensions of a stimulus.
- Stockings of Cambridge (SOC) task. Is a spatial planning task based on the Tower of Hanoi task. The SOC task examines the ability to rearrange colored balls in a lower display to match a goal arrangement in an upper display in the least number of moves possible.
- Spatial working memory (SWM) task. Examines the ability to retain spatial information in working memory and also assesses search strategy.

Synonyms

Cambridge neuropsychological test automated battery

Description

CANTAB is a computerized battery of cognitive-neuropsychological tests that is marketed by Cambridge Cognition. The CANTAB website is www.cantab.com.

CANTAB is promoted as having some of the following features that can be beneficial for use in research (see <http://www.cantab.com/cantab-for-academic-research.asp>):

- Computer touch-screen administration
- Independent of culture

Historical Background

Information about the CANTAB can be found on the CANTAB website at www.cantab.com. The

CANTAB is currently produced and marketed by Cambridge Cognition. The CANTAB was founded by Dr. Trevor W. Robbins at the University of Cambridge and Dr. Barbara J. Sahakian at the Section of Old Age Psychiatry, Institute of Psychiatry, in the United Kingdom and their colleagues (Robbins and Sahakian 2002). The development of the CANTAB was based from cognitive neuropsychological paradigms in animals in order to examine components of cognitive function in humans (beginning with the elderly) and deficits in patients with dementia (Alzheimer's disease); performance on the CANTAB has been linked to the frontal and temporal lobes of the brain (Robbins et al. 1998).

The CANTAB has been used to examine aspects of cognitive function in over 100 psychiatric and neurologic diseases and disorders including Alzheimer's dementia, anxiety disorders, attention deficit hyperactivity disorder, autism spectrum disorder, Parkinson's disease, and schizophrenia. Please see <http://www.cantab.com/disorders.asp> for a full listing of disorders that have been examined using the CANTAB.

The CANTAB was first used in research studies involving individuals with autism in the mid-1990s. Publications on the CANTAB in individuals with autism can be found in the "References and Reading Section." Results on the CANTAB in autism show that the intradimensional/extradimensional (ID/ED) set-shifting task, the Stockings of Cambridge (SOC) task, and the spatial working memory task from the CANTAB have been useful in detecting impairments in executive functioning in individuals with autism; however, there is some inconsistency in the literature on whether deficits are always found in all of these tasks. In addition, performance on the ID/ED, SOC, and SWM tasks from the CANTAB has been examined in siblings as well as in parents of children with autism. The results in siblings showed while there were no group differences in overall means, a subset of the siblings showed deficits at the ED stage on the ID/ED task and difficulty in passing the higher-level planning problems

on the SOC task (Hughes et al. 1999). Parents of children with autism showed impairment on all three of the CANTAB tasks of executive function (fathers in particular, were more impaired on the SOC planning task, Hughes et al. 1997).

Psychometric Data

Normative data on the CANTAB are available for individuals 4–90 years of age in four IQ ranges. (See CANTAB website www.cantab.com for information about norms; also see DeLuca et al. 2003; Luciana and Nelson 2002; Robbins et al. 1994, 1998).

Test-retest reliability data for CANTAB tasks are also available (Cambridge Cognition 2008; Lowe and Rabbitt 1998). Data on the Standard Error of Prediction (SEP) are also available on CANTAB tasks in order to be able to calculate a confidence interval for determining whether a retest score is due to a real effect or a measurement error (Cambridge Cognition 2008).

Clinical Uses

In autism, the CANTAB has generally been used as a research tool rather than for clinical use.

There is one publication in the literature that has used the CANTAB to examine changes following rehabilitation in autism. The study reported changes in executive function abilities on the Stockings of Cambridge planning task and the Spatial Working Memory task in adults with autism following participation in a vocational rehabilitation program compared to prior to enrolling the program (Garcia-Villamizar and Hughes 2007).

Short Description or Definition

Capgras syndrome is a particular type of delusional misidentification characterized by the inability of recognizing someone (usually a loved one, a close relative, or friend) as the person they claim to be. In this monothematic delusion, the individual recognizes overtly and straightforwardly who that person is meant to be, upholding however a firm belief to the contrary, which is anchored in subjective cues such as an eerie feeling that something is not quite right about that person, complete lack of a sense of familiarity, and missing the proper affective response. Individuals with Capgras syndrome cling to the unshakeable belief that the original person in question was replaced by an impostor, who cunningly is trying to fool them – with no success at all because, of course, they *know* better. The nature of this alleged impostor, an almost exact double, usually is human, but in some cases, it may turn out to be ghostly, alien, or robot. As a consequence of the puzzling dissonance between “looking familiar” and “feeling familiar,” this is

often referred as a most extraordinary and uncanny experience (Young 2009). There is no emotional connectedness whatsoever to the putative impostor, and so a sense of suspicious estrangement ends up prevailing. Therefore, the overall clinical picture is dominated by an intense paranoid tint. A combination of depersonalization (an alteration in the experience of self in which the individual experiences his/her own body or mental activity as changed in quality to become unreal, detached, or automatized) and derealization (an alteration in which it is the individual’s surroundings that are experienced as remote, lacking immediacy, and oddly unreal) is not unusual in the earlier stages of the syndrome (Munro 2009). Sometimes, individuals with Capgras syndrome become enraged and act on their delusion, attacking the “impostor” with violence. But it may also happen that their relationship with the impostor follows the same pattern of the one with the original person.

Categorization

The eponym “Capgras syndrome” was proposed by the French psychiatrist Joseph Levy-Valensi, in 1929 (Blom 2010). The name refers to Jean Marie Joseph Capgras, who described in 1923, in collaboration with Jean Reboul-Lachaux, the case of a psychotic patient who believed that her husband, her children, other inmates, and hospital staff had been replaced by successive and numerous “doubles” or physically identical impostors (Capgras and Reboul-Lachaux 1923). Capgras and Reboul-Lachaux themselves referred to this phenomenon by the French term *illusion des sosies* (illusion of doubles). The patient they described also believed that she herself had many doubles and, in addition to the “delusion of doubles,” she had persecutory and grandiose delusions. However, a narrower connotation for the Capgras syndrome, referring only to the delusional misidentification, gradually evolved (Rodrigues and Banzato 2006).

Even though the classic form of the Capgras syndrome involves the replacement of persons, there are interesting variations in which pets, objects, or even places (such as one’s own

house) are replaced by copies or duplicates. Thus, the syndrome could be further specified by adding the indication of whom or what has allegedly been replaced; there would be then Capgras syndrome for persons, for animals, for objects, for places, etc. The Capgras syndrome is one of the four main delusional misidentification syndromes described in the psychiatric literature, and unlike the other three (Frégoli syndrome, intermetamorphosis syndrome, and the syndrome of Subjective Doubles) where false and positive identification (hyperidentification) phenomena occur, it is marked by false and negative identification (hypoidentification). The Frégoli syndrome is characterized by a delusional false recognition; in short, the individual identifies familiar persons in strangers. The body may be different, but there is no doubt about the presence of the psychological identity of a familiar person. The latter has changed completely his/her physical appearance or taken over someone else's body, a most radical form of disguise (usually with malevolent intentions). In intermetamorphosis, the individual comes to believe that people around have exchanged their identities, so each person involved in this delusional plot becomes somebody else. In the syndrome of the subjective doubles, the individual is convinced of the existence of exact doubles of him/herself (Munro 2009). It has also been described reverse forms of both Capgras and Frégoli syndromes. In the reverse Capgras, the own self of the individual is taken as a sort of psychological impostor, inhabiting a body that does not belong to him/her. In the reverse Frégoli, the psychological identity of one's own self is preserved alongside with radical changes in his/her physical makeup (Rodrigues and Banzato 2006). Delusional misidentification may be a symptom of several psychiatric (most frequently) and neurologic illnesses, or a separate syndrome on its own right. When misidentification takes place in the context of schizophrenia, severe mood disorder, or dementia, it is regarded as a feature of that illness and it should be referred to as a misidentification phenomenon rather than the syndrome in question. But when a delusion such as the ones aforementioned is the principal and most conspicuous aspect of a

psychosis and other conditions can be ruled out (see differential diagnosis below), it should be assigned as a subcategory within persistent delusional disorder (ICD-10) or delusional disorder (DSM-IV) (Munro 2009). Some classify Capgras phenomenon into either "primary," when associated with psychiatric illnesses, or "secondary," when the phenomenon occurs in the context of a neurologic disorder (Barton 2003).

Epidemiology

Estimates of the prevalence rate of Capgras syndrome vary, depending on the settings and facilities where the investigations are carried out. Currently, the syndrome is claimed to be more common than previously assumed, ranging from 1.3% up to 4% of psychiatric inpatients – with lower frequencies being reported in emergency rooms and in private psychiatric practice. Special populations seem to be particularly at risk to develop Capgras syndrome at some point in the course of their illnesses. Prevalence rates as high as 15–40% in patients with schizophrenia and 2–30% in patients with Alzheimer's disease have been reported. Data regarding sex ratio are conflicting, showing either an even distribution of cases or an increased frequency among women – up to twice the frequency found among men (Tamam et al. 2003; Henriët et al. 2008).

Natural History, Prognostic Factors, and Outcomes

The age of onset, course, and outcomes of Capgras syndrome vary, depending on the underlying neuropsychiatric condition. Among psychiatric patients, Capgras delusion may either be present at the clinical onset of the mental disorder or, more frequently, appear later on, after years of evolution. Remission of this delusion may precede the overall clinical improvement, be simultaneous with it or only be achieved after the abatement of other symptoms. The delusional misidentification may also persist in the long

run. When patients with schizophrenia and mood disorders are compared to each other, the latter are seemingly less prone to have unremitting misidentifications and to hold them for longer than the acute phase of the illness (Christodoulou 1978).

Clinical Expression and Pathophysiology

Several theories have been formulated in order to explain the Capgras syndrome, and among them, we have both the psychological comprehensive (in the sense of taking into account meaningful connections within the individual's life and circumstances) and the cognitive neuropsychiatric ones. As they typically share the view that the core emergent phenomenon in Capgras syndrome is the puzzling dissociation between the proper objective recognition of a given percept and a distorted sense of familiarity towards it, it should be recognized that these theories may not be mutually exclusive. Instead, they can even be seen as complementary to each other in some cases, however, with different emphasis, which is placed either on the psychological dynamic aspects or on the neural underpinnings of the phenomena.

Psychodynamic and Other Psychologically Comprehensive Theories

The fact that patients with Capgras syndrome sometimes report feelings of strangeness in respect to both their surroundings and themselves has fostered the hypothesis that experiences of derealization and depersonalization could play a role in the emergence of the Capgras syndrome and other delusional misidentification syndromes. According to this hypothesis, derealization and depersonalization might be conceived as roots to the distorted feelings of familiarity usually held by patients towards their acquainted ones. Whether this distortion is a direct consequence of derealization and depersonalization, or a response to these symptoms, the delusion of substitution is often thought of as having a somewhat appeasing

effect on the individual by explaining away the rather uncomfortable and perplexing experience of unreality (Christodoulou 1991).

Another comprehensive hypothesis about the genesis of this curious phenomenon revolves around the alleged presence of unacceptable or ambivalent feelings toward a close person. A split on such person's identity would then take place in the patient's mind as a means to circumvent the conflict. For example, someone holding unconscious aversive feelings towards his parents would be allowed, by means of the Capgras delusion, to experience unambiguous love and respect towards them, while, at the same time, directing the otherwise unacceptable feelings of despise, hate, distrust, or fear to the "impostors" (Enoch 1986). Similarly, the syndrome could possibly develop in the context of changing interpersonal relationships, when experiences of strangeness and unconscious negative feelings towards a given person might emerge more easily. The ultimate consequence would be the belief that this close person is not who he or she seems to be but an impostor (Berson 1983).

Additionally, the syndrome has also been thought to result from a pathological regression to archaic models of thinking, arguably common in primeval stages of human evolution, possibly inherited by all of us, when the idea of doubles and the theme of dualities in general were usual (Todd 1957).

Cognitive Neuropsychiatric Theories

In contrast to purely psychological and psychodynamic theories, the emphasis given by cognitive neuropsychiatric approaches to the neural underpinnings of Capgras syndrome, whether well-established or still hypothetical, paves the way for putting forward testable hypothesis, improving thus the empirical anchorage of such theories. As these approaches heavily rely on analogies with other conditions where disrupted face recognition processes definitely or presumably occur, such as prosopagnosia, reduplicative paramnesia, autistic disorder, and Asperger syndrome, heuristic gains should be expected.

Several models of this sort have already been proposed, each one of them positing different hypothetical mechanisms that would lead to these diverse, though correlated, phenomena.

One of these models was first presented by Joseph (1986). According to it, putative cortical interhemispheric disconnections would respond for the distortions on the familiarity feelings experienced by patients towards known persons. Dissociation between cerebral hemispheres would lead to two different and segregated images of the percept – one of them produced by analytic strategies in the left hemisphere and another one produced through more global processing in the right hemisphere. These two images would suffice for the patient to recognize the physical features of known people, but their dissociation would also engender a very strange twofold experience of the percept, suitable to delusional interpretation. Nevertheless, individuals with corpus callosum agenesis or those who suffered section of this commissure for treatment of severe epilepsy do not seem to be particularly prone to develop Capgras syndrome, which weakens Joseph's hypothesis.

A more elaborated and highly regarded hypothesis to explain Capgras syndrome was articulated by Ellis and Young (1990), underpinned by Bauer's (1984) postulation of distinct pathways for overt and covert face recognition. According to Bauer, face recognition would involve two different processes and neuroanatomic pathways. A ventral route connecting the visual associative cortex to temporal lobes (especially amygdala) via inferior longitudinal fasciculus would be critical for overt or conscious face recognition. On the other hand, a dorsal route connecting visual associative cortex to cingulate gyrus and hypothalamus via superior temporal lobe and inferior parietal lobule would function as a kind of covert system for the recognition of faces. The latter would not in fact allow someone to know whose is the face seen in a given moment, nor determining whether it is familiar or not. Instead, the authors argue that this route would be relevant in assigning affective significance to faces. Bauer's proposal follows from the observation that one of his patients with bilateral occipito-temporal damage and suffering from

severe prosopagnosia – the impaired ability to recognize previously known faces and learn new ones – could still show distinctive skin conductance responses when pictures of known faces presented to him were paired with their correct names or wrong ones. Although incapable of telling if those faces were known to him, or even guessing the correct face/name pairing, this patient's autonomic responses were taken as indicative that covert recognition was present and, probably, provided by a mechanism independent from the one responsible for overt recognition. This surprising integrity of autonomic responses to unrecognized known faces in prosopagnosic patients has been confirmed by other authors (Tranel and Damasio 1985).

Based on Bauer's distinction, Capgras syndrome, according to Ellis and Young (1990), could be conceived as a clinical and anatomic-functional mirror image of prosopagnosia. While in prosopagnosia, overt recognition pathways are supposedly disrupted and covert recognition route is claimed to be intact, the inverse would arguably happen in Capgras syndrome. In the latter, adequate appraisal of structural and dynamic facial features, as well as correct evocation of related semantic information, would be guaranteed by ventral route proper functioning. At the same time, dorsal route malfunctioning would prevent the patient to ascribe the expected affective tone to familiar faces. Such a strange mismatch would then stimulate rationalization and support the delusional belief that an impostor has replaced an acquainted person.

Departing from Bauer's two-route model of face recognition, as well as from its use by Ellis and Young (1990) to explain Capgras syndrome, Breen et al. (2000) point out that there is very little evidence that the dorsal visual pathway play any role in visual recognition – either in animals or in humans – and even less in ascribing emotional significance to visual percepts. In contrast, they state that inferotemporal area and amygdala, relevant structures in the ventral visual pathway, are respectively regarded as critical in matching seen faces to stored representations and to the emotional responses these faces might evoke. They propose that malfunctioning of the ventral visual

pathway alone may explain both prosopagnosia and Capgras syndrome. As to Capgras syndrome specifically, their suggested explanation is that the activity of ventral visual recognition structures in the ventral temporal lobe would be normal, but it somehow fails to trigger the activity of ventral limbic structures. This would happen due to either a disconnection between these structures or to impairments within the ventral limbic structures.

Perceptual abnormalities engendered by inadequate visual processing of facial features had been also posited as the fundamental dysfunction in Capgras syndrome. Together with clinical and test-generated evidence that patients with Capgras syndrome often present sub-prosopagnosic face recognition defects, the fact that some of them have been reported to show full-blown prosopagnosia and brain damages that include those seen in prosopagnosic patients has led to the so-called prosopagnosia hypothesis for Capgras syndrome. However, each of these alleged links between the two conditions must be taken cautiously. Accumulated evidence indicates that if there is some sort of relationship between prosopagnosia and Capgras syndrome, it is unlikely to be a straightforward one. It seems that at best, there is a heuristically fruitful analogy, such as the one rendered by the models proposed by Ellis and Young (1990) and by Breen et al. (2000).

Two other hypotheses are worth mentioning, as they depart from the emphasis usually given to experiences of depersonalization/derealization, perceptual dysfunctions, or to a primarily disrupted ability to attach familiarity feelings to known faces. One of them, originated from the observation of delusional misidentifications in schizophrenic patients, postulates that in order to be identified and evoke familiarity feelings, a given percept must be subjected to a process of integration of its various perceived features and stored representations. Such integration would be critical for ascribing percepts with a sense of “uniqueness,” a key element for their identification (Margariti and Kontaxakis 2006). This hypothesis had been explored by Cutting (1991), to whom the loss of that sense of “uniqueness” would be related to right

hemisphere dysfunction (allegedly present in schizophrenic patients) and subsequent failure in perceiving and processing information globally. A second theory has postulated that Capgras syndrome, as well as reduplicative paramnesia, would be possibly related to a failure in updating stored representations of an object, thus leading to a mismatch between its currently seen characteristics and those remembered by the patient (Staton and Brumback 1982).

Finally, it must be stressed that the delusional character of Capgras syndrome cannot be explained by the dysfunctions postulated at the core of any of the enlisted theories alone, and this is sometimes acknowledged by their very proponents. Indeed, derealization, depersonalization, and perceptual abnormalities often occur in the absence of impaired reality testing. Likewise, it is argued that even the puzzling experience of missing the affective overtones expected in the sight of a close person should not be so promptly taken as a sufficient condition for a delusion. Accordingly, the fact that patients with Capgras syndrome fail to conceive less unreasonable explanations to their experiences than the existence of an impostor, as well as to revise their odd beliefs despite evidence in contrary, is sometimes suggested to indicate that altered reasoning and disrupted monitoring of decisional processes play a significant role in the clinical picture. If there is actually an altered experience in the encounter with a close person, then a two-stage model for Capgras syndrome may be needed, one accounting for the odd experience itself and another accounting for the creation and maintenance of a delusional explanation for such experience (Barton 2003; Gainotti 2007; Coltheart et al. 2010).

Structural and Functional Brain Findings

Structural abnormalities in brain CT and MRI scans, as well as EEG and functional brain imaging alterations, have been found not only in cases of neurologic Capgras syndrome but, very often, also in those considered to be primary psychiatric cases. These injuries have been shown to be either

diffuse or localized (often numerous) and not rarely a superposition of both. In most cases, the findings are located in the frontal lobes, sometimes exclusively, but frequently in association with abnormalities affecting other brain areas. Right hemisphere is significantly most often affected, as compared to the left hemisphere. This pattern is consistent with the role postulated for the frontal lobes in the genesis of reasoning and decision-making biases that may give a delusional status to abnormal familiarity feelings.

A variety of conditions has been found to be causes of the structural and functional abnormalities mentioned, including tumors, head trauma, strokes, infections, EEG paroxysmic discharges, and metabolic and neurodegenerative disorders (Barton 2003; Gainotti 2007; Devinsky 2009).

Evaluation and Differential Diagnosis

The assessment of individuals with Capgras syndrome is basically clinical, as it happens with delusions in general. Phenomenal experience, i.e., the way a particular content is subjectively experienced by the individual (in this case, the certainty that a replacement has occurred), is the key domain of the clinical evaluation. Compared to other types of delusions (such as persecutory and mystic or religious), it is easier to have Capgras syndrome's delusional character promptly acknowledged by everyone around, due to the clear impossibility of content (hence its classification as a "bizarre delusion"). It is also important to ascertain how broad and systematic the delusion in question is if it is really a monothematic one or just a small part of an overarching delusion. Furthermore, full assessment of all other areas of psychopathology, including consciousness, attention, memory, perception, thinking, language and speech, mood, and motor activity, is required for the sake of differential and precise diagnosis.

It is relevant to identify if Capgras phenomenon occurs in the context of schizophrenia (or schizophrenia spectrum disorders), in other kinds of delusional disorders (where pure Capgras delusion should be included), or in major mood disorders with delusion (Berson 1983). Moreover,

Capgras phenomenon is often associated with organic brain disorders (about one fourth to one third of the cases), such as brain tumors and infarcts, head trauma, subarachnoid hemorrhage, and basilar migraine, so a complete neurological investigation should be carried out in all cases (Barton 2003). Substance-related disorders must be suspected as well, and the history of substance use needs to be properly checked out; laboratory screening tests for drugs may be run as a supplementary measure. Regardless the final diagnosis reached, a careful and comprehensive assessment must be performed to estimate the actual risk of the individual with Capgras syndrome (or more broadly, Capgras phenomenon) acting on such delusion, as, understandably, the putative impostor constitutes an obvious target for violence.

Treatment

To date, no specific treatment is available to Capgras syndrome. When it is part of the clinical picture of some particular medical condition, interventions aiming at the basic disorder should be the first choice. The delusional character of the syndrome prompts the use of antipsychotics. Psychological approaches are unlikely to make the delusion disappear but may be useful to make patients less concerned, isolated, and dysfunctional because of their pathological beliefs. Good estimates of treatment response in Capgras syndrome are not available. Although it is reasonable to assume that prognosis of delusional misidentification will depend on the underlying medical or psychiatric condition, it must be kept in mind that high response rates may be achieved in the treatment of delusions in general, even when they are part of a delusional disorder (typically regarded as having poor therapeutic response) (Munro 2009).

Care Pathway for Children and Adolescents with Autism Spectrum Disorder on an Inpatient Psychiatric Service

Paige Cervantes

Department of Child and Adolescent Psychiatry,
Child Study Center, NYU Langone Health,
New York, NY, USA

Definition

The Autism Spectrum Disorder Care Pathway (ASD-CP) was designed to address the challenges associated with providing care to youth with ASD psychiatrically hospitalized in nonspecialized

settings. The ASD-CP, first implemented in July 2015 in a public hospital, consists of a modular staff training, a set of behavioral intervention strategies focused on prevention and management of challenging behaviors (CBs), and a toolkit to aid in staff implementation of strategies. Data collected in 3 years since its inception suggests that the ASD-CP is associated with significant reductions in the use of crisis interventions in patients with ASD.

Historical Background

Youth with ASD are psychiatrically hospitalized at elevated rates compared to age-matched peers. These youth also have significantly longer hospital stays, and the costs associated with hospitalizing children with ASD are more than double the costs for children without ASD (Croen et al. 2006). Risk factors for hospitalization in ASD include greater adaptive impairments, higher ASD symptom severity, presence of CB, comorbid psychiatric concerns (specifically mood disorder and obsessive-compulsive disorder), concurrent sleep problems, and being of older age or in a single caregiver home (Mandell 2008; Righi et al. 2017). Despite the high prevalence of individuals with ASD receiving inpatient psychiatric services, with over 10% of caregivers reporting that their child with ASD has been hospitalized at least once (Mandell 2008), and the substantial financial resources expended on hospitalization, standard inpatient care frequently fails to meet the unique needs of the autism population.

In general, psychiatric units are designed for verbal, typically developing individuals with acute mental illness, primarily internalizing disorders, and common treatments, such as process groups and family meetings, rely heavily on verbal and social skills. Therefore, the needs of individuals with ASD admitted to the hospital, most frequently for externalizing behavior (i.e., aggression, property destruction, self-injury; Siegel et al. 2012), are often extremely disparate from the typical patient. The inherent social communication and interaction impairments make commonly

used inpatient interventions inaccessible to individuals with ASD. Inpatient care is also complicated by restricted, repetitive behavior symptoms. While schedule changes and frequent staff transitions are common in general psychiatric units, youth with ASD perform best when following a predictable routine with familiar caregivers. Sensory features of the hospital setting (e.g., harsh lighting; novel, unpredictable noises) may also contribute to increased agitation. When patients with ASD present with comorbid intellectual disability (ID) and/or severe language impairments, difficulties with communication are exacerbated, impeding further on medical and psychiatric assessment and treatment and often on staff ability to understand and meet even the basic needs of their patients. Further, hospital personnel at various levels (e.g., direct care workers, child psychiatrists) often report having limited experience and training in ASD, generating further concern regarding both the appropriateness of the services delivered and patient and staff safety (McGuire and Siegel 2018).

In recent years, several specialized inpatient psychiatric units serving exclusively youth with ASD and/or ID have been developed and have demonstrated effectiveness. Specialized units are distinct from general settings in that they provide staff training focused on improving knowledge about the diagnosis of and treatments for ASD/ID; comprehensive medical, developmental, psychiatric, and behavioral assessment to patients; and a biobehavioral approach to treatment where both applied behavior analysis (ABA) and pharmacological interventions are applied. An extensive multidisciplinary team works collaboratively to address patient symptoms and typically includes a child psychiatrist, psychologist, board-certified behavior analyst, occupational and speech therapists, nurses, social workers, and special educators. Specialized units are also equipped with tools to enhance communication (e.g., visual supports), to protect patients and staff in the case of CB (e.g., personal protective equipment), and to meet the sensory needs of children with ASD (e.g., quiet areas). Importantly, most specialized units provide some sort of continuum of services, including care in residential,

intensive day treatment, partial hospitalization, school, and outpatient settings, addressing barriers related to limited options for appropriate follow-up care post discharge (Siegel et al. 2012; Taylor et al. 2019). Though length of stay is longer in specialized units, patients hospitalized in this setting have statistically significantly reduced symptom severity from admission and are less likely to visit the emergency department (ED) within the first 2 months following discharge than patients with ASD psychiatrically hospitalized on general units (Gabriels et al. 2012; Siegel et al. 2014; Taylor et al. 2019).

Unfortunately, only approximately ten specialized units in the country exist and are predominantly located in the Northeastern United States. Consequently, a majority of children with ASD in need of psychiatric hospitalization are currently served within general settings. While the prevalence of specialized units is increasing (Siegel et al. 2012), creating a separate, specialized psychiatric unit for many hospitals, particularly those with limited resources, may not be feasible. Therefore, efforts to improve ASD services in general psychiatric inpatient settings are essential and should occur in tandem with work to expand availability of specialized units. To address this need, experts convened and provided discussion and recommendations on essential components of ASD services that are feasible for integration within general settings. These recommendations were:

1. Obtain detailed information from caregivers about patient preferences, functioning, and presenting problem.
2. Assess first for a potential medical cause of the presenting concern (e.g., pain, medication side effects).
3. Provide comprehensive psychiatric and developmental evaluation as well as evidence-informed pharmacotherapy linked to the resulting diagnostic picture.
4. Evaluate and accommodate communication, sensory, motor, and adaptive behavior needs.
5. Conduct a functional behavior assessment to identify maintaining variables of CB.
6. Provide developmentally appropriate activities and a sensory-friendly environment.
7. Continue educational demands during hospitalization to facilitate the eventual transition back to school.
8. Conduct ASD-specific direct care staff training (McGuire et al. 2015).

While these experts agreed that it is possible to adequately care for youth with ASD within general inpatient units when appropriate accommodations are in place, limited research exists examining the impact of the accommodations on service provision and patient outcome. Therefore, with these recommendations and in collaboration with clinicians in specialized psychiatric units, a multidisciplinary team at a public hospital in New York developed the ASD-CP, a clinical care model aimed at improving inpatient services for youth with ASD served on a general inpatient psychiatric service.

Current Knowledge

The ASD-CP consists of a four-module staff training and toolkit outlining a variety of intervention strategies. Internal supervising psychologists or nurses provide the training once per quarter to all new staff across disciplines, including but not limited to technicians, nurses, and attendings. Each module of the staff training is 45 min long and uses a variety of teaching strategies, such as didactics, video examples, role-plays, and interactive exercises. The first training module defines ASD and presents integral foundational intervention principles, such as first making sure patients' basic needs are met (e.g., assess for the presence of pain/hunger/thirst). The following three modules present key evidence-informed behavioral treatment components of the ASD-CP using the acronym PATHWAY (i.e., Module 2, Predictability, Activity; Module 3, Total communication, High reward; Module 4, WAY to cope). The modular format of the staff training allows for presentation of material over the course of several days or as a comprehensive one half-day training.

The toolkit, which is provided in the form of a three-ring binder to increase portability, builds on the strategies presented in the training and includes a tip sheet, visual supports for patients, and staff supports. Of note, staff interact with the toolkit during the training to facilitate gains in fluency prior to its use with patients on the unit. The tip sheet is an efficient, one-page assessment filled out at admission by parents or guardians. Primarily using a checkbox format, the tip sheet gathers information about how a child communicates and understands language, the topography and antecedents of CB, and patient preferences in activities, calming strategies, rewards, and foods. The back of the tip sheet is reserved for staff to communicate with other personnel any helpful information gathered about the patient throughout their stay. Visual supports include a visual schedule and first-then card, used to enhance communication between staff and patients as well as improve patient compliance and transitions, and a coping card, used to prompt the patient to engage in a calming activity at early signs of agitation to prevent worsening of CB. The stimuli used for the visual supports are pulled from a sizeable bank of laminated images of activities and items typically present during hospitalization (e.g., meet with doctor, lunch, play with ball). A multidisciplinary team worked together to develop the image bank and first piloted the images on the units before including them in the toolkit. Staff supports include a list of developmentally appropriate leisure activities and a staff schedule. The staff schedule lists the order of leisure and therapeutic activities throughout the day with activities of daily living (e.g., toileting, eating) included. At the top of the staff schedule, staff indicate the patient's safety goal and the reward the patient will receive if their safety goal is met. The safety goal is chosen by the treatment team and typically relates to reducing CB and/or increasing adaptive behavior. Checkboxes are used to indicate whether the patient met the requirement for a reward and are presented alongside the schedule of reinforcement for meeting the safety goal (e.g., absence of hitting for 15 min intervals is rewarded with access to iPad).

Patients eligible for the pathway have ASD, no-to-minimal verbal language, and require 1:1 staffing, as per the clinical judgment of the admitting physician, most often due to high levels of CB and/or low levels of adaptive functioning. These eligibility criteria resulted from discussions regarding patient need and organizational feasibility. At the patient level, difficulties associated with adapting to the nonspecialized inpatient setting were hypothesized to be greatest in patients with limited language, substantial adaptive impairments, and severe CB. These youth typically have higher ASD symptomology and, secondary to severe CB, are also at increased risk for crisis interventions. On the provider level, the ASD-CP involves many components of evidence-informed intervention that would be most feasible to provide in the context of 1:1 care.

The ASD-CP is implemented within the pediatric psychiatric acute care program at a public hospital in New York. The acute care program consists of a Children's Comprehensive Psychiatric Emergency Program (CCPEP) and three child and adolescent psychiatric inpatient units. When youth present to the hospital in psychiatric crisis, they are evaluated in the CCPEP. Based on physician evaluation, these youth may be discharged if they do not require further stabilization, admitted for observation to the CCPEP's six-bed brief-stabilization unit where they may be observed for up to 72 h, or admitted directly to one of the psychiatric inpatient units. When a child arrives to the CCPEP, the evaluating physician determines if the child meets criteria for the ASD-CP, and, if they do, the physician asks the caregiver to complete the one-page tip sheet. If the child is then admitted to the brief-stabilization or inpatient unit, the tip sheet along with the toolkit follows the child. Ideally, when preparing for discharge, caregivers of admitted youth are instructed on ASD-CP strategies, and materials used during the inpatient stay are shared.

In regard to evidence of effectiveness, the initial study compared outcomes of first time admits who received the ASD-CP in the 18 months following initiation of implementation to those who would have met criteria to receive ASD-CP but

were admitted in the 18 months prior to its initiation. Initiation of the ASD-CP was associated with a significant reduction in holds and restraints in both brief-stabilization and inpatient settings. Further, a 40% decrease in total length of stay approached statistical significance in this small, initial study (Kuriakose et al. 2018). A subsequent study was then conducted to examine the sustainability of these results, adding a third comparison group of youth who received the ASD-CP in the 18 months following the initial implementation period. Results from this study demonstrated that reductions in the use of crisis interventions, including holds, restraints, and intramuscular medications, were sustained, while the non-statistically significant trend toward decreased length of stay was no longer present (Cervantes et al. 2019). Taken together, current data suggest that the ASD-CP can be implemented and sustained with limited resources and minimal expertise and is associated with improved patient care.

Future Directions

While the results of significant and continued reductions in crisis interventions are exciting and essential, research into the ASD-CP requires further development. First, these initial studies were small, and the samples were heterogeneous. Therefore, replication across sites and with larger samples is needed to improve confidence in the effects of the ASD-CP. We also do not currently have documented evidence of intervention fidelity. However, the process of data abstraction from medical records across the first two studies exposed inconsistent use of some of the ASD-CP tools, particularly those that required documentation (e.g., staff schedule). Although it is undeterminable how ASD-CP components that do not require documentation (e.g., first-then card, simplifying language) were implemented, the inconsistent use of those that do suggests that the improvements seen may be due to a milieu change, such that changes in staff self-efficacy and understanding are responsible for the reductions in their use of crisis interventions (Cervantes

et al. 2019). A more formal evaluation of how patient care and outcome relates to staff fidelity on ASD-CP intervention components and staff acceptability of ASD-CP strategies is currently underway. Importantly though, because fidelity estimates are captured by record review, we are limited by a lack of formal documentation of use across strategies. Therefore, we are now creating a feasible process for assessing implementation of tools and strategies across each staff shift using a brief fidelity checklist. Improved understanding of intervention acceptability and fidelity, and how these factors might influence patient care and outcome, will allow us to identify key components of the ASD-CP and thus pare down the intervention to increase feasibility. Subsequently, staff supports will be further developed to encourage consistent implementation of essential components. For instance, we will be adding periodic booster training sessions for all retained staff.

Further, as reported, the ASD-CP was designed for a distinct subpopulation of the autism spectrum. However, youth with ASD who do not meet criteria for the ASD-CP also require thoughtful adaptations to treatment as usual in psychiatric inpatient settings. Future research should assess the utility and feasibility of implementation of ASD-CP strategies for youth of varying severity levels and presentations. Of note, presenting concerns may differ between and within groups of youth who do and do not meet criteria for the ASD-CP. For example, it is not uncommon for youth with ASD to present with internalizing symptoms, such as anxiety, post-traumatic stress disorder (PTSD), depression, and/or suicidality (Siegel 2018). These individuals would likely require variations in programming that are distinct from both the ASD-CP and treatment as usual. Additional resources for assessing and addressing the unique needs of these children in non-specialized psychiatric inpatient settings are required.

Finally, researchers have found that psychiatric hospitalization in specialized settings is associated with lower recidivism rates for youth with ASD (Gabriels et al. 2012). It is essential that we also study long-term outcomes for patients who receive the ASD-CP. While it is promising there

were demonstrated improvements in care during their stay, understanding if and how the ASD-CP improves patient utilization trajectories and transitions to less restrictive care environments post discharge is integral and would have significant public health implications given the high costs associated with hospitalization. Readmission rates are often elevated in this population of children, as demonstrated by the proportion of youth excluded from evaluation due to readmission status (~10%) across our studies (Kuriakose et al. 2018). While quality of care during psychiatric hospitalization contributes to this, readmission rates are also largely driven by the considerable lack of appropriate community supports available for patients to transition to after their stay. This systemic issue of limited accessibility of supports increases both the prevalence of psychiatric hospitalization and the economic burden of ASD. Importantly, researchers have found that higher spending on ASD-specific outpatient services and on respite care in particular was associated with significant reductions in the likelihood of psychiatric hospitalization (Mandell et al. 2012, 2019). Therefore, not only are improvements in inpatient care necessary, but it is essential that we continue to work to increase accessibility to evidence-based treatments and family supports to prevent hospitalization and keep youth with ASD integrated in the community.

Caregiver Consent to a Pediatric Neurodevelopmental Research Registry

Luke Kalb

Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Kennedy Krieger Institute's Center for Autism and Related Disorders, Baltimore, MD, USA

Definition

There has been a historical lag in the development of evidenced-based interventions for youth with neurodevelopmental disorders (NDD), including those with autism spectrum disorder (ASD). One well-known barrier to the development of empirically sound interventions is research recruitment. Problems with study recruitment and retention can result in the delay and/or termination of intervention studies. This methodological problem can also result in the selection of study participants who are not representative of the target population, leading to biased study estimates. Recruitment of youth with NDD can be particularly challenging, when compared to the neurotypical

population, since the caregiver will have to simultaneously manage the child's extensive healthcare needs alongside participating in a research protocol.

One potential solution to improve recruitment to NDD studies is through the use of research registries. There are many types of registries, including national or international disorder-specific registries as well as registries that recruit from a particular clinic or institution (hereafter referred to as clinic registries). Joining a clinic registry, which is governed under an institutional review board, offers parents the opportunity to hear about and potentially engage in local research opportunities. For the investigator, it provides a low-cost option to actively recruit participants, rather than simply relying on passive recruitment methods (e.g., flyers, word of mouth).

There is evidence to suggest that most caregivers raising a child with or at risk of NDD are agreeable to joining a clinic registry, when offered the opportunity during their child's evaluation. This finding is valuable as it speaks to parent's overall interest in joining the research enterprise. However, this conclusion is drawn from the only known study of this topic.

There also appears to be disparate trends across settings in terms of the proportion of families who consent to join the clinic registry. Settings that primarily serve the ASD populations, rather than those serving youth with NDD as a whole, may find increased registry consent rates over time. There are many possible reasons for this finding, including the nature of the setting. If it is a one-time evaluation center, families may be less interested at the prospect of an ongoing research relationship compared to a setting where their child may be receiving care over an extended period of time. There may be something unique to the ASD population as well. There are numerous national organizations and initiatives that have brought science to the general conscious of the ASD community, including the federally funded Autism Act, the Simons Foundation SPARK project, and Autism Speaks. These disparate efforts may have created a culture of scientific collaboration not seen in other populations.

Family sociodemographic factors play an important role as to whether families consent to a clinical registry. For the caregiver, race and socioeconomic status likely influence their decision. Race and ethnicity, in particular, may be related to medical mistrust given the historical research injustices (e.g., Henrietta Lacks) faced by people of color. The nature of the clinical registry, which elicits consent to contact for an unspecified prospective project, may exacerbate feelings of mistrust since caregivers are providing consent to hear about an unknown endeavor. Lastly, families with low income may be less likely to consent since they may not have the resources (e.g., ability to travel) or time to become involved in a research project.

Beyond sociodemographics, it is likely the child's clinical characteristics influence caregiver's interest in research. There is evidence to suggest that caregivers of children with increased mental health issues may be more apt to consent. This may reflect the parents desire to enroll in a study that could assist with such problems or the desire to help other children like theirs. It would follow that increased core developmental issues, such as the presence of increased ASD symptoms, would be positively related to caregiver consent, just like mental health symptoms. However, increased ASD severity has not been associated with an increased likelihood of registry consent. There is research to suggest that these core developmental issues are less stressful to caregivers than the presence of behavior problems. Perhaps the consent findings mimic this body of research on stress.

Much more research is needed on trends and predictors of consent to clinic registries involving youth with NDD. Qualitative approaches that identify reasons for consent, or lack thereof, are particularly needed. This work would shed light on the speculative reasons, put forth above, for why particular populations are more or less likely to consent. Future research should also seek to replicate the existing findings, identify novel predictors of consent, and examine this topic among other pediatric populations.

Carnosine

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

beta-Alanyl-L-histidine

Definition

Carnosine is a compound formed from two amino acids (histidine and alanine) and is found in several organ systems including muscle and brain. A number of possible biological roles for this compound have been suggested including antioxidant properties. It has been used experimentally

in several disorders. One small double-blind study in 2002 by Chez and colleagues reported positive initial findings, although the study was criticized on various grounds and the results have not yet been well replicated in the scientific literature.

Synonyms

[Case report](#)

Definition

Case studies are frequent in both biomedical and behavioral psychological research. A typical case study (sometimes referred to as case report) provides a focused report of an individual or series of individuals to illustrate some important issue relevant to clinical work or research. Many of the conditions now recognized as significant causes of developmental disability first appeared as case reports, for example, Down syndrome and childhood autism. Sometimes case reports are used to draw attention to other relevant issues, for example, new approaches to treatment. Case studies from the behavioral literature may be used to illustrate the possible effectiveness of a new intervention, for example, the subject is used as his/her own control with data collected pre-, during, and postintervention. In other fields such as business or law, case studies take other formats.

Case studies may be primarily descriptive or may be more theoretical in nature. Sometimes, as in the case of Down syndrome (trisomy 21), the underlying theory may prove profoundly wrong but the observation is very robust (in the case of Down syndrome, the report from Dr. Down appeared well before there was any awareness of the importance of human chromosomes in development and disease). Case studies can bring attention to new phenomena, can serve as a vehicle for teaching or documenting a potentially important clinical issue, and may, over time, lead to more focused hypothesis-based research. As noted, single-subject research methods provide possibilities for statistically based evaluation within a report focused on a single case.

While case studies have importance in focusing attention on new observations and stimulating hypothesis testing and theory building, they also have some important limitations. Various factors can go into the selection of the case that is reported, and generalization is therefore difficult. There is an obvious tendency on the part of editors and reviewers to support positive association reports (rather than negative ones) in case studies and again generalization can be limited. Cases

may also be reported with these multiple publications of the same case contributing to a perception of greater significance than actually is apparent. As a result, many journals now have limited publication of case reports.

One example in the autism research is provided by the many case reports of autism associated with a host of medical conditions ranging from congenital infections, inborn errors of metabolism, obstetrical risk, and so forth. As noted by Rutter et al. (1994) in the 1970s and early 1980s, there were frequent reports of such associations, but the value of such reports was limited given a lack of relevant controls for issues of diagnosis, duplicate reporting, issues in assessment, and lack of comparison groups. Rutter and colleagues emphasized the importance of controlling for these factors and adopting a more epidemiologically based approach in evaluating reports of comorbid associations of autism with these conditions. When this was done, the strongest associations were with a handful of genetic conditions (fragile X and tuberous sclerosis) and with seizure disorder.

Casein

Madison Pilato

Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Synonyms

Milk protein

Definition

Casein is a milk protein. One type of casein found in human and cow milk, beta-casein, is digested into beta-casomorphins (BCMs). Sun et al. (1999) demonstrated that BCMs affect many regions in the rat brain (i.e., nucleus accumbens, caudate, putamen, ventral tegmental and median raphe nucleus, and orbitofrontal, prefrontal, parietal, temporal, occipital, and entorhinal cortices). These effects are partially blocked by opiate receptor antagonists, indicating that BCMs act like opioids in the mammalian nervous system. Additionally, infusion of BCM has been shown to cause behavioral changes in rats including restlessness followed by inactivity, reduced response to sound, and reduced social interaction (Sun and Cade 1999). These results are used to support to the opioid-excess theory (Panksepp 1979) to explain the symptoms of autism. According to this theory, BCMs become excessive because of an enzyme deficiency (Trygstad et al. 1980; Reichelt et al. 1981) or a leaky gut (Wakefield et al. 1998), and the opioid effects in the human nervous system contribute to the symptoms of autism. However, well-designed studies have not found

abnormal opioid concentrations (Cass et al. 2008) or evidence for GI abnormalities in individuals with autism (Buie et al. 2010; Fernell et al. 2007; Sandhu et al. 2009).

Despite a lack of support for either the enzyme deficiency or leaky gut theory, the opioid-excess theory has led to a focus on eliminating casein, and often gluten, from the diets of children with autism. Most studies have examined a combined gluten-free, casein-free diet. Therefore, it is difficult to assess the effect of eliminating casein alone. However, one study (Lucarelli et al. 1995) did find improvement on five out of seven behavioral scales in children adhering to an only casein-free diet compared to a control group with no dietary restrictions. Worsening on two out of seven of the scales was also observed after a casein challenge. However, the study design had many limitations. Notably, a small sample was studied, and it is unclear if the behavior evaluators were blinded to the diet status of the participants. In addition, no other studies have eliminated only casein. More research and replications are needed before casein-free diets can be considered efficacious. Gluten-free, casein-free diets also lack scientific support. In a 2008 review, Millward, Ferriter, Calver, and Connell-Jones reported mixed results for gluten-free, casein-free diets, with most studies having major methodological limitations and the better designed studies reporting mostly negative findings. Without adequate data, elimination diets are currently not recommended (Buie et al. 2010).

Catatonia

Amita Shah

The NAS Lorna Wing Centre for Autism,
Bromley, Kent, UK

Catatonia, Shutdown and Breakdown in Autism

Catatonia is a complex neuropsychological disorder which can affect individuals with autism spectrum disorder (ASD), including those with high-functioning autism and Asperger syndrome. Most clinicians think about catatonia as a historical and outdated psychiatric disorder and find it difficult to recognize the ways catatonia can manifest in autistic individuals. In autistic individuals, the most severe acute and classic form of catatonia as described in the psychiatric literature can occur but it is rare (Billstedt et al. 2005; Wing and Shah 2000). Manifestations of catatonia in autistic individuals are usually gradual, chronic, and can occur together with shutdown, overall deterioration of functioning, and breakdown. The terms “autism-related catatonia” and “autistic catatonia” are useful to enable clinicians to conceptualise catatonia differently in autistic individuals differently in autistic individuals and distinguish it from general catatonia in the psychiatric literature.

Types of Catatonia Manifestations in Autism

1. Chronic catatonia and catatonia-type deterioration and breakdown
2. Catatonia with shutdown
3. Episodic catatonia type difficulties
4. Acute classic catatonia (rare)

Detailed descriptions of the varied manifestations and case examples are provided in Shah (2019).

The possibility of catatonia should be considered in any autistic individual who shows a marked and obvious deterioration in voluntary movement, speech, level of activity, and independence compared to previous levels (Shah 2019; Wing and Shah 2000).

Possible Early Signs

- “Freezing” or marked hesitations during movement or action
- Slowing down in movements, actions, and/or speech
- Tendency to “shutdown” in overwhelming situations
- Increased reliance on verbal or physical prompts

Common Manifestations and Symptoms

- Increased slowness affecting movements and speech
- Marked reduction in the amount of speech or selective/complete mutism
- Difficulty in initiating and inhibiting actions
- Increased reliance on physical or verbal prompts
- Increased passivity and increased social withdrawal
- Periods of “shutdown”
- Physical or mental freezing episodes lasting minutes or hours

Other Manifestations and Associated Behaviors

These can include difficulty crossing thresholds and transitions, to and fro movements and hesitations, odd stiff posture, parkinsonian features, and episodes of excitement and agitation. There can also be a marked increase in repetitive and ritualistic behaviors.

Secondary Difficulties and Consequences

These include the following:

- Social and communication withdrawal
- Inability to cope with everyday demands and life
- Inability to attend school, college, work, etc.
- Challenging behavior and “meltdowns” due to the frustration of not understanding what is happening to them – this can spiral down to autistic breakdown
- Mobility issues and muscle wastage
- Secondary medical and physical problems

Summary of Key Aspects of Autism-Related Catatonia

(based on research studies and clinical experience)

- Catatonia can affect autistic children (as young as 6 years) and adults of any age.
- The current prevalence rates of catatonia in ASD based on systematic prevalence studies range between 17% and 20% (Billstedt et al. 2005; Breen and Hare 2017; Wing and Shah 2000).
- Catatonia can affect individuals across the whole spectrum including those with intellectual impairment as well as those who are intellectually high-functioning. There are research projects in the pipeline exploring catatonia-associated phenomena such as “inertia” and initiation difficulties which are experienced by many high-functioning autistic individuals.
- Autistic individuals with a “passive” type of social impairment are more likely to have a breakdown in the form of catatonia (Wing and Shah 2000).
- There can be huge variation in symptoms and manifestations in the same individual at different times and in different situations. Some high-functioning autistic individuals show “episodic” catatonia difficulties causing temporary “shutdown” or “freezing” and/or mutism.

- In many individuals, catatonia can occur together with a more general breakdown which can be referred to as “autistic breakdown.”
- At this point in time, we do not have a complete picture of the types and manifestations of catatonia and shutdown in autism. New subtypes are coming to light by clinicians as awareness is increasing.
- Detailed psychological assessment of the person’s underlying autism and possible stress factors
- Eliminating possible culprits such as antipsychotic medication
- Designing a person-centered multidimensional plan of management which reduces the stress and motivates the individual. This includes looking at the individual’s program, environment, occupation, lifestyle, activities, and making changes as needed

Assessment

The general catatonia rating scales are not appropriate for screening or assessing the manifestations of autism-related catatonia. The author recommends a dimensional assessment to gather information from various sources to obtain an individual profile of catatonia-related manifestations and the secondary difficulties. The Autism Catatonia Evaluation (ACE-S) (Shah 2019) has been developed to guide clinicians and researchers.

Interventions and Management

Psycho-Ecological Approach

This is not a specific intervention but a multidimensional approach which has evolved through clinical experience and has been found to be extremely useful and beneficial for individuals and their families at various levels (Shah 2019; Shah and Wing 2006). The aim of this approach is to understand and formulate the individual’s catatonia in the context of their underlying autism, vulnerability and sensitivity, identification of possible causes and stresses, and developing a multidimensional treatment and management plan.

The main components of this approach are listed below. A detailed description and application of the psycho-ecological approach with case examples can be referred to in Shah (2019).

The main components of this approach include the following:

- Timely diagnosis of catatonia-like deterioration at an early stage
- Psycho-education and training
- Providing 1:1 support with specific strategies
- Providing external stimulation and increasing participation with support
- Management of specific problems and secondary consequences
- Psychological interventions and support for high-functioning autistic individuals, for example, adapted Cognitive Behaviour Therapy (CBT), mindfulness, anxiety management training.

Further general and specific psychological intervention and management is described in DeJong et al. (2014); Dhossche et al. (2006b); Hare and Malone (2004); Shah and Wing (2006); and Shah (2019).

Caution About Medical Interventions

There is a very limited literature based on individual case reports and small case series describing effects of medical treatments of catatonia in autistic individuals. These report a range of psychiatric medications, doses, and effects. Most of these reports concern severe, acute manifestation of catatonia in autistic individuals. These have been documented and reviewed in the paper by DeJong et al. (2014). As pointed out by the authors, the outcomes should be interpreted cautiously for various reasons. In general, there is huge individual variation in response to medical treatments used in treating catatonia in autistic individuals. Clinicians warn against the use of antipsychotic medication and generally recommend the use of

benzodiazepines (Dhossche et al. 2006a; Mazzone et al. 2014).

Clinicians who use medication to treat catatonia symptoms in autistic individuals should do with extreme caution and be mindful of the possibility of the side effects of the medication which can trigger catatonia symptoms or make them worse. Medication which is carefully tailored and monitored may be useful as an emergency treatment for acute, severe catatonia or as a short-term treatment trial in selected cases. Before, during, and after medical treatment, it is important to continue using the psycho-ecological approach and strategies for supporting the individual and their families/carers.

Short Description or Definition

22q11.2 deletion syndrome (22q11.2DS) is diagnosed in individuals with a submicroscopic deletion of chromosome; 22. 22q11.2DS encompasses phenotypes previously described as CATCH22, which is an acronym for cardiac defect, abnormal facies, T-cell deficit, cleft palate, and hypocalcemia due to chromosome 22q11 deletion. These are variable features associated with several clinically defined syndromes, including DiGeorge, velocardiofacial, and Takao, that are now recognized to be the same condition with a common cause.

Categorization

The acronym CATCH22 was suggested in the 1990s to encompass the variable features that accompany 22q11 deletion (Wilson et al. 1993).

Clinical diagnoses associated with 22q11 deletion include DiGeorge syndrome, Shprintzen (velocardiofacial) syndrome, and Takao (conotruncal anomaly face) syndrome. These phenotypes were recognized independently due to the prominence of particular clinical features. Identification of a common 22q11 deletion among patients with any of these diagnoses provided the clear unifying factor for these clinically defined syndromes.

An absent thymus and hypocalcemia due to a small parathyroid were the first recognized features of DiGeorge syndrome, establishing the diagnosis in the 1960s (Kirkpatrick and DiGeorge 1968). Additional characteristics including facial features and heart defects were noted as reports of the syndrome accumulated. DiGeorge syndrome is now recognized by a pattern of structural or functional deficits of the thymus, reduced parathyroid function, decreased serum calcium, and congenital heart defects.

Shprintzen, or velocardiofacial syndrome (VCFS), includes palate abnormalities, a characteristic facial appearance, and, in some cases, heart disease (Shprintzen et al. 1978, 1981). Additional features of VCFS include learning disabilities, developmental delay, and a wide array of psychiatric disorders (Motzkin et al. 1993).

Takao, or conotruncal anomaly face syndrome, is identical to DiGeorge syndrome, but the Japanese group was the first to recognize the major contribution of outflow tract defects of the heart (Takao et al. 1980).

In 1981, de la Chapelle and colleagues reported that an unbalanced translocation between chromosome 22 and another chromosome was associated with features of DiGeorge syndrome. The small deletion created by the chromosome rearrangement led to the hypothesis that genes in this region of chromosome 22 were responsible for DiGeorge syndrome (Augusseau et al. 1986). Further prospective analysis of patients with DiGeorge syndrome confirmed the importance of 22q11 deletion in this population, though additional chromosomal abnormalities were found in a few cases (Greenberg et al. 1988). Targeted chromosome studies in patients with VCFS (Driscoll et al. 1992, 1993; Kelly et al. 1993; Scambler et al.

1992) or Takao syndrome (Burn et al. 1993) revealed a similar proportion of 22q11 deletion in these phenotypes as well. A 1.5- or 3-Mb piece of 22q11 is typically lost (Cohen et al. 1999; Jerome and Papaioannou 2001).

Burns suggested using DiGeorge syndrome for the severe presentation at birth, VCFS for children with a prominent craniofacial presentation, and Takao syndrome when cardiovascular features are prominent, with the CATCH phenotype encompassing all of the three diagnoses (Burn 1999). It is now recognized that these clinically defined phenotypes are variable features of the same condition associated with 22q11.2DS (Kobrynski and Sullivan 2007).

Epidemiology

22q11.2DS is the most common microdeletion syndrome. It occurs in about 1 in 2,000 to 1 in 6,000 children and accounts for 2% of all heart defects (Liling et al. 1999; Botto et al. 2003). This is the second most frequent cause of congenital heart disease after Down syndrome. In the United States, as many as 700 infants may be affected annually, with a slightly higher prevalence in Hispanics (Botto et al. 2003). Given the variable expression of 22q11.2DS, the incidence is likely to be higher than estimated.

More than 90% of patients have a de novo deletion of 22q11.2 (McDonald-McGinn et al. 2015).

Natural History, Prognostic Factors, and Outcomes

22q11.2DS is associated with premature mortality, with death occurring within the first year for 4% of all affected infants. Though death is often associated with congenital heart disease, the overall mortality for individuals with 22q11.2DS surpasses that for individuals with non-syndromic forms of similar heart defects (Repetto et al. 2014). Recurrent infections occur across the lifespan. Speech difficulties can abate with therapy and surgery to correct palate abnormalities.

Clinical Expression and Pathophysiology

Congenital heart disease occurs in 75% of individuals (McDonald-McGinn et al. 2015). Associated cardiac malformations typically affect the outflow tract. These include tetralogy of Fallot, type B interrupted aortic arch, truncus arteriosus, right aortic arch, and aberrant right subclavian artery.

Palatal abnormalities occur in 75% of individuals. These include velopharyngeal incompetence, submucosal cleft palate, bifid uvula, and cleft palate. Only 11% of patients with 22q11.2DS have cleft palate, while 65% have more mild palatal abnormalities (McDonald-McGinn et al. 2015).

Immunodeficiency occurs in 75% of individuals. This includes abnormal T-cell production, chronic infection, impaired antibody production impacting vaccine response, allergy and asthma, and other autoimmune disorders (McDonald-McGinn et al. 2015). It can be secondary to absent or impaired thymus development. In infancy, most patients have T-cell counts below age-appropriate levels, which often improves within the first year.

Hypocalcaemia due to hypoparathyroidism occurs in 50% of individuals. In affected infants, hypocalcaemia frequently resolves within the first year, though it can occur at any age, including adulthood (Wilson et al. 1993; McDonald-McGinn et al. 2015).

Facial features include a small mouth, square nose tip with pinched nostrils, unusual earlobe folding, short upper lip folds, and slanting eyes (Wilson et al. 1993).

Gastrointestinal abnormalities are found in 30% of individuals, which can result in feeding and swallowing difficulties (McDonald-McGinn et al. 2015).

Mild to moderate learning difficulties and speech and language delay are common. Autism spectrum disorder is found in 20% of children. Various psychiatric disorders, including paranoid schizophrenia and major depressive illness, have also been described in 25% of adult cases (Motzkin et al. 1993; McDonald-McGinn et al. 2015).

Hearing loss, cleft lip, kidney abnormalities, and low-functioning thyroid can also occur, though these features are less common (Wilson et al. 1993).

Evaluation and Differential Diagnosis

Distinctive facial features together with a heart defect affecting the major outflow tract defect or a history of recurrent infection should raise suspicion. When these features are not present, diagnosis can be missed.

A chest X-ray is necessary for immunological assessment. However, identifying a small thymus by radiography can be challenging in stressed infants. Children with 22q11.2DS may have normal white blood cell counts, while sick infants may instead have a normal thymus and reduced white blood cell counts. To resolve these differences, assess the number of CD4-positive T lymphocytes. Sick infants should be treated as if they have compromised cellular immunity, with transfusion using irradiated blood to avoid graft-versus-host disease until diagnosis is confirmed (Wilson et al. 1993).

Suspicion of 22q11 deletion syndrome should be confirmed using a molecular genetics test. Routine cytogenetic studies can exclude major chromosomal rearrangements, while fluorescent in situ hybridization, multiplex ligation-dependent probe amplification, or copy number variation analyses can more precisely determine deletion size and location. Parents should be screened for carrier status; 10–25% of parents may be asymptomatic carriers (Levy et al. 1997).

Treatment

Clinical management is complex due to the array of phenotypes associated with 22q11.2DS. Heart defects are usually the focus of treatment, though this treatment does not differ from that for other similar heart defects. Early echocardiography is critical in any child with suspected 22q11.2DS.

Hypocalcemia can be treated using calcium supplements and 1,25-cholecalciferol.

The child should be examined for the presence of a submucous cleft, which can elude detection and often requires surgical intervention.

Immunological features manifest as frequent respiratory infections in early childhood with few occurrences of severe immunodeficiency. Early thymus transplantation has been performed to alleviate immunological features, though these features may resolve on their own over time (Markert et al. 1999).

Early diagnosis and intervention for psychiatric illnesses can improve long-term prognosis. Standard treatments for attention deficit, anxiety, and schizophrenia are effective.

Catecholamine System

Alex Bonnin

Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Structure

The most abundant catecholamines are epinephrine (adrenaline), norepinephrine (noradrenaline), and dopamine. Catecholamines are produced from phenylalanine and tyrosine.

Dopaminergic System

Dopamine is produced by neurons in the substantia nigra, the ventral tegmental area, and hypothalamus. These neurons project to many areas of the brain, including the prefrontal cortex, the amygdala, the hippocampus, and striatum. Dopamine released by the hypothalamus also acts as a neurohormone, inhibiting the release of prolactin from the anterior lobe of the pituitary. In the periphery, dopamine is also produced in the adrenal medulla. Dopamine activates five known types of receptors (D1–D5).

Function

Norepinephrine and dopamine act as neuromodulators in the brain and also as peripheral hormones in the blood circulation. Norepinephrine is a neuromodulator of the peripheral sympathetic nervous system.

Central catecholamine function is important for regulating many behaviors, e.g., cognition, movement, sleep, mood, attention, and learning.

In the periphery, catecholamine release increases heart rate, blood pressure, and blood glucose, generally associated with the response to an environmental stressor.

Pathophysiology

Abnormally high levels of central and peripheral catecholamines can be caused by trauma (brainstem), neuroendocrine tumors (e.g., for the periphery in the adrenal medulla – a condition known as pheochromocytoma). Monoamine oxidase A (MAO-A) deficiency can also lead to elevated levels of central and peripheral catecholamines.

Catechol-O-Methyltransferase

Alex Bonnin

Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Synonyms

[COMT](#)

Definition

Enzyme that catalyzes the O-methylation of catecholamine neurotransmitters and catechol hormones, leading to their inactivation.

There are two known isoforms:

A membrane-bound isoform (MB-COMT) and a soluble cytoplasmic isoform (S-COMT).

Structure

Anatomical Structure

The caudate nucleus, along with the putamen, globus pallidus (GP), subthalamic nuclei, and substantia nigra (SN), makes up a larger collection of nuclei called the basal ganglia. The two caudate nuclei, each residing within a hemisphere, sit alongside the lateral ventricles, superior to the thalamus, and laterally bound by the internal capsules. Its C-shaped structure consists of three identifiable regions: (1) the bulbous “head” lying ventral to the putamen and forming the anterior horn of the lateral ventricle, which tapers to (2) the long, curved “body” which moves posteriorly forming the floor of the lateral ventricle and then curves anteriorly to end at (3) the thinner “tail” near the posterior end of the thalamus and forming the roof of the temporal horn of the lateral ventricle. The tail, or *cauda* in Latin, is the namesake for this structure.

The caudate nucleus and putamen together form the striatum (or neostriatum). Although these two structures share embryonic origin, starting as a single nuclear mass, they develop into anatomically distinct structures divided by the internal capsule. Yet, the internal capsule does not completely separate the caudate nucleus from the putamen. At the head of the caudate nucleus, a striated cell bridge, made up of gray matter extensions, joins the caudate nucleus to the putamen, thus giving its name “striatum.” The striatum (caudate nucleus and putamen) and the GP comprise the corpus striatum. Furthermore, the ventral portion of the caudate nucleus, the putamen, nucleus accumbens, and anterior perforated substance make up the ventral striatum. These classifications are used to differentiate structure, afferent and efferent projections, associated neurotransmitters, and functions.

Histology

The majority (~90%) of the neurons that make up the caudate nucleus are efferent spiny dendrites which release gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter. The remaining neurons, those without spines, connect internally and use the excitatory neurotransmitter, acetylcholine (ACh).

Neural Connections

Like the other basal ganglia nuclei, the caudate nucleus has a multitude of nerve connections, serving important and widespread functions, which will be discussed in greater detail in the next section. Here, the major afferent (excitatory) and efferent (inhibitory) projections will be discussed.

Afferent (or Input) Nuclei: The major afferent connections are from the cerebral cortex and substantia nigra. The corticostriatal connection (from the cerebral cortex to the caudate nucleus) originates primarily from the frontal and association cortices, in particular the prefrontal and parietal regions. (The putamen in comparison receives its projections from the primary motor, premotor, supplementary motor, and somatosensory cortices.) All afferent connections are excitatory and glutamergic. Additionally, these afferent connections are ipsilaterally and topographically organized, such that within the same hemisphere, the frontal lobe inputs onto the head of the caudate nucleus, the parietal and occipital lobes onto the body, and the temporal lobe onto the tail.

Efferent (or Output) Nuclei: The major efferent connections of the caudate nucleus are to the internal and external segment of the globus pallidus (GPint and GPext, respectively) and the substantia nigra pars reticulata and compacta (SNr and SNc, respectively). The striatopallidus (from the striatum to the globus pallidus) and striatonigral (from the striatum to the substantia nigra) efferents are inhibitory and GABAergic. The GPint efferents then project to the thalamus, enervating the dorsomedial nucleus, intralaminar nuclei, and parts of the ventral anterior nuclei. The SNr efferents project to the superior colliculus (SC) of the eye and the ventral anterior and ventral lateral thalamic nuclei.

Intrinsic (or Internal) Nuclei: The GABAergic inhibitory striatopallidal and striatonigral connections are not the only intrinsic connections within the striatum. Nigrostriatum connections (originating in the SNr and projecting to the striatum) are dopaminergic may have either excitatory or inhibitory effects, depending on which type of receptor the neurotransmitter binds.

Pathways

The afferent and efferent neurons of the caudate nucleus (and putamen too) participate in the direct and indirect feedback loop pathways of the thalamus, having either excitatory or inhibitory effects, respectively. In the direct pathway, the inhibitory GABAergic effect of the efferent neurons releases the GPint from inhibition, thus creating a net excitatory reaction. Alternatively, in the indirect pathway, GABA from the striatum inhibits the GPext and has downstream effects in the subthalamic nuclei and the GPint, ultimately leading to a net inhibitory effect. Thus, whether the caudate nucleus is involved in engaging or inhibiting an action depends on which pathway wins out (DeLong 2000).

Furthermore, the caudate nucleus may also have excitatory or inhibitory effect in the cortex via dopaminergic neurons within the nigrostriatal pathway. The depolarization (stimulation) or hyperpolarization (inhibition) of a cell is highly dependent on the dopamine receptor on the postsynaptic terminal.

Function

Most of our knowledge of the functionality of the caudate nucleus come from a variety of animal studies, human lesion studies, and more recently, functional magnetic resonance imaging (fMRI). The caudate nucleus, which was once thought to have its influences limited to the sensorimotor system, is now known to be heavily involved in executive function, memory, and even some aspects of social communication. Consequently, most of the caudate's role in sensorimotor functioning, except for that of higher-level control, has since be re-established as being the role of the putamen (for review, see Middleton and Strick 2000).

From a cognitive perspective, convincing evidence points toward the caudate nucleus contributing to goal-oriented behavior (Grahn et al. 2008). Goal-oriented behavior is the appropriate stimulation of action and the selection of goals (and subgoals) based upon the expected outcome of the specific action. Thus, cognitive flexibility

and set-switching between goals become very important in goal-oriented behavior. In animal lesion and neurochemical studies, the caudate nucleus has been directly linked to the rats' ability to change or switch between choices, as it seen in reversal learning tasks (Ragazzino 2003; Ragazzino and Choi 2004), and strategies (Ragazzino et al. 2002; Yin et al. 2005) when task contingencies change (e.g., which item is rewarded, the value of the reward, schedule of reward). Furthermore, the caudate nucleus has been found to be selectively responsible for adapting to these new task contingencies and executing the appropriate switch rather than inhibiting the proponent response as the prefrontal cortex does (Dias et al. 1996). In primates, single-unit recording from the caudate nucleus revealed different patterns depending on whether the expected outcomes of the action are positive or negative (Ravel et al. 2003). Similarly, human neuroimaging evidence has found stronger activation responses in the caudate nucleus to positive reinforcement. In addition, greater activation was seen within the caudate nucleus when subjects thought they had subjective control over the outcome (Grahn et al. 2008). Thus, the caudate nucleus is necessary for both the behavior (the process of selection) and the evaluation of the outcome (choice).

This role in goal-oriented behavior and reward-based learning is not surprising given the caudate nucleus' modulation of dopamine, which is known to be heavily involved in the reward systems (Cools et al. 2009), abundance of dopamine receptors, and influence in updating information during working memory tasks (Frank and O'Reilly 2006). Essentially, the caudate nucleus is active in a constant loop of evaluating feedback, deciding what to do based upon that feedback (e.g., maintaining vs. switching response), and stimulating (or inhibiting) other regions via its multiple neural pathways to execute a response which will provide further feedback to the caudate nucleus.

Social/Language Processing: It is difficult to completely differentiate the caudate nucleus' role in social aspects and language processing from its role in the higher-order cognitive functions

discussed above. For instance, it is not surprising that neuroimaging and lesion studies have found that social rewards activate the caudate nucleus, given the fact that this structure responds similarly to monetary, and even expected (but not necessarily received), rewards (Izuma et al. 2010; Montague et al. 2002; Villablanca 2010). Involvement in social behavior is likely limited to and selectively involved in behavior associated with action-outcomes but may have important implications in social motivation which is reliant on assessing social reward.

In terms of language, evidence shows that the caudate nucleus plays may pay a role in the higher-level language processing involved in bilingualism and deciphering phonemes and meaning of words in ambiguous situations (Crinion et al. 2006). This finding was left-side unilateral which is to be expected as language function as a whole is predominately localized to the left hemisphere. Although its contribution to language processing is not directly related to action-outcome or goal-directed behavior, the caudate nucleus continues to have a critical role in situations which require an active selecting process to yield the best outcome. Here, the caudate nucleus helps determine which phonemes and/or definitions make the most sense given previous knowledge and current context.

In conclusion, the caudate nucleus is highly involved in higher-order cognitive functioning, especially in learning and memory tasks that are highly dependent on reinforcement. Its predominant role in goal-oriented behavior has been shown in rodent, primate, and human studies.

Pathophysiology

Given the structural and functional significance of the caudate nucleus, and the known executive dysfunction in autism, it is not surprising that this structure has been implicated in the pathophysiology of the disorder. Morphological, genetic, and neuroimaging studies have found evidence of abnormalities within the caudate nucleus of individuals with autism and its associated disorders. Although not all results are

consistent with each other, especially in relation to the behavioral and clinical correlates of autism, abnormalities within the caudate nucleus have been repeatedly found and likely contribute in some way to the aberrant functioning of individuals with autism and its associated disorders.

Morphological data has shown a bilateral enlargement of the caudate nucleus in individuals with autism when compared to healthy control groups (Cody Hazlett et al. 2009; Hollander et al. 2005; Langen et al. 2007, 2009; Sears et al. 1999), which remains significant even when total brain volume is taken into account. The volumetric increase (Langen et al. 2009) as well as outward deformation (Qiu et al. 2010) of the caudate nucleus has been localized to the head of the structure. Only one study (Langen et al. 2009) found unilateral malformation, with a significantly greater volumetric increase in the right caudate nucleus. Langen and colleagues additionally found that caudate volume has an atypical developmental trajectory (2009). Caudate volume increased with age in individuals with high-functioning autism compared to the inverted U-shape trajectory in typical development, peaking between the ages 7 and 8. Due to this atypical development, the greatest differences in caudate volume were seen at later ages (Langen et al. 2007, 2009). It should be noted, however, that not all studies have documented this increase in caudate volume (Langen et al. 2011). Age, specific diagnosis, intellectual functioning, and the current or previous usage of medication may have contributed to these nonsignificant findings.

At a microscopic level, Singh and Rivas documented that serum antibodies, which were not present in healthy controls, were most commonly present in the caudate nucleus (49%) of children with autism, compared to the cerebral cortex (18%) and cerebellum (9%; 2004). Although they argue that this supports an autoimmune theory of autism, more importantly, it illustrates an additional abnormality within the caudate nucleus as well as the heterogeneity of these abnormalities.

Additional atypical physiology has been found in the functional connectivity between the caudate nuclei and cerebral cortex (Turner et al. 2006). In a

functional connectivity MRI (fcMRI) study, age-matched males with autism showed decreased connectivity between the right caudate nucleus and occipital-temporal regions but increased connectivity between bilateral caudate nuclei and contralateral motor cortices compared to controls within (Turner et al. 2006). Taken all together, individuals with autism show an aberrant neural organization, which likely contributes to autism's phenotypic expression given the caudate nucleus' role in initiating direct and indirect pathways.

Given the caudate nucleus' diffuse connections throughout the brain via the direct and indirect pathways, this disrupted functional connectivity may have important implications in the executive dysfunction of autism, yet fMRI studies implicating the caudate nucleus have been relatively sparse and inconsistent. Silk and colleagues found reduced activation of the caudate nucleus in individuals with autism compared to controls during a mental rotation task, a paradigm known to rely heavily on executive functioning and working memory (2006). This finding, however, has not been replicated in other tasks relying on visuospatial skills and working memory (Luna et al. 2002). Alternatively, this group found the caudate nucleus to be involved in sensorimotor control associated with saccadic eye movements in individuals with autism but not healthy control individuals. They suggest that the caudate nucleus, as well as other structures within the frontal-striatal circuit, is recruited during saccadic eye movements as a compensatory mechanism due to a defective sensorimotor system (Takarae et al. 2007). If individuals with autism use the caudate nucleus for lower-level functions, like saccadic eye movements, then there may be less resources available for the caudate nucleus to perform higher-level cognitive tasks, like those associated with goal-oriented behavior.

Some of the most intriguing findings are not from those found in individuals with autism but those found in individuals with the genetic disorders associated with autism (see fragile X syndrome and Rett syndrome). Individuals with fragile X syndrome (FXS) not only have an increased caudate nucleus size when compared to controls (Cody Hazlett et al. 2009; Gothelf et al.

2007; Hoefft et al. 2008; Reiss et al. 1995) but also when compared to individuals with non-FXS autism (Cody Hazlett et al. 2009). The Cody Hazlett study further broke down their results to analyze the subgroups of FXS individuals with and without autism compared to autism non-FXS individuals and controls. Their results showed that both FXS groups (those with and without autism) had significantly enlarged caudate nucleus volumes compared to the autism and control groups, and there was no significant difference in the caudate volume between the two FXS groups (Cody Hazlett et al. 2009). This latter finding suggests that although both FXS and autism have been linked to enlargement of the caudate nucleus, this effect is not additive. Such that individuals with both FXS and autism do not have a greater increase in volume of the caudate nucleus. Alternatively, it may mean that individuals with both an autism and a FXS diagnosis have a greater probability of having an enlarged caudate nucleus compared to those individuals with a single diagnosis. Yet, since not all individuals with FXS have autism nor do all individuals with FXS or FXS with autism have enlargements of the caudate nucleus, it is hard to determine how these physiological abnormalities behaviorally manifest themselves in each disorder.

In comparison, age- and gender-matched girls with Rett syndrome showed smaller volumes of the caudate nucleus when compared to controls (Subramaniam et al. 1997). It should be noted, however, that although Rett syndrome is characterized by autistic-like behavior, the study did not indicate whether these individuals had a diagnosis of autism or not. Thus, a decreased caudate volume may be specific to Rett syndrome and not to autistic behavior, however this has been examined.

Although the above studies contribute significantly to the autism literature and begin to delineate the neurophysiological abnormalities in autism, only a few have examined how these structural differences may express themselves phenotypically. Langen and colleagues found significant negative correlations between caudate volume and insistence on sameness (IS) on the

ADI-R (or difficulty changing minor routines; 2009). This is consistent with Sears and colleagues finding negative correlations between caudate volume and higher-order repetitive behaviors (ADI-R C2 algorithm items), including the same IS factor as Langen et al. (2009). Interestingly, a significant positive correlation was found between low-order repetitive behaviors (stereotyped movements) and caudate volume (Sears et al. 2009). These correlations with repetitive behaviors, however, are not consistent. Two groups (Hollander et al. 2005; Rojas et al. 2006) found positive correlations between caudate volume and higher-order repetitive behaviors. These inconsistencies as well as the nonsignificant findings make discussion of this literature. Examining all the results together reveals, at least, some relationship between caudate nucleus enlargement and phenotypic behavior in individuals with autism.

In conclusion, although the caudate nucleus has been implicated in the pathophysiology of autism and its associated genetic disorders, results are relatively inconsistent. Morphological data supporting an enlargement of the caudate nucleus in individuals with autism remains the most replicated, but even these results are not always in agreement, especially when in relation to diagnostic criteria. Findings from the FXS and Rett syndrome studies may have important implications in the genetic pathophysiology of autism and should be examined in greater detail. Additionally, given the known functional importance of caudate nucleus in behavioral flexibility and reversal learning, known to be affected in autism, more studies should aim to identify where the functional abnormalities of the caudate nucleus are in individuals with autism. At this time though, despite inconsistencies in the literature, the caudate nucleus remains an important structure when examining the etiology of autism due to its significant structural, neurochemical, and functional connections.

Ceiling Effect

Domenic V. Cicchetti
Departments of Psychiatry and Biometry, Yale
Child Study Center, Yale University, New Haven,
CT, USA

Definition

This phenomenon occurs when a test item is so easy that a large number of test takers achieve the highest score possible on that item. Another way of viewing the phenomenon would be to describe such easy items as ones that fail to distinguish

between levels of ability of the test takers. If nearly all or all testees get the Vineland adaptive behavior item right, then it is a useless item, from a psychometric perspective and must never see the light of clinical brightness.

CELF Preschool – 2

► [Clinical Evaluation of Language Fundamentals: Preschool – Second Edition \(CELF Preschool-2\)](#)

CELF-5

Monica Barreto
Yale Child Study Center, New Haven, CT, USA

Description

The *Clinical Evaluation of Language Fundamentals–Fifth Edition* (CELF-5; Wiig et al. 2013a) is a battery of tests designed to assess, diagnose, and measure changes in oral and written language and verbal and nonverbal communication in individuals 5–21 years of age. The CELF-5 can be used to identify strengths and weaknesses in language, determine service eligibility, provide intervention strategies, and measure intervention efficacy. The CELF-5 is individually administered by speech-language pathologists, school psychologists, special educators, and diagnosticians with training and experience in administration and interpretation of individually administered standardization language tests and knowledge of language structure rules.

The CELF-5 provides the flexibility of administering only the tests needed to answer referral questions for assessment and evaluation. Thus, the testing process can be individualized to meet a student's unique needs, their functional language, and the language behaviors in both clinical and educational settings (Wiig et al. 2013b). Across settings, assessment begins with gathering

information regarding the presence of a language disorder and/or a student's language performance at school and at home. The CELF-5 provides that Observational Rating Scale (ORS), as a tool to systematically document observations as a means to provide descriptive information to help develop plans for intervention.

Diagnostic Battery

The CELF-5 provides a better balance of items across receptive and expressive modalities, language content, and overall structure than its previous editions (Wiig et al. 2013b). It has been developed and researched to enable examiners the flexibility of using each group of items independently (e.g., Linguistic Concepts, Semantic Relationships, and Understanding Spoken Paragraphs) of one another. The CELF-5 battery includes revised tests from previous editions as well as new tests used to evaluate word meaning and vocabulary (semantics), word sentence structure (morphology and syntax), the rules of oral language used in responding to and conveying messages (pragmatics), the recall and retrieval of spoken language (memory), and a new test used to evaluate aspects of literacy (reading comprehension and written language production) (Wiig et al. 2013a).

Administration

As a result of the flexibility in administration, the average length of administration for the CELF-5 can vary across referral questions and age groups. Administration of the Core Language tests takes approximately 34 min for ages 5:0–8:11 and 42 min for ages 9:0–21:11. Administration of the tests needed to derive the Receptive Language Index takes an additional 16 min on average for ages 5:0–8:11, and 9 min for ages 9:0–21:11. No additional time is required to derive the Expressive Language Index for ages 5:0–8:11, as all required tests for this index are part of the Core Language Score. Additionally, in order to derive the Expressive Language Index, an additional 12 min is needed for ages 9:0–21:11. Overall, in order to administer the Core Language, Receptive Language, and Expressive Language Indexes, administration takes an average of 50 min for ages 5:0–8:11 and 62 min for ages 9:0–21:11.

Once the CELF-5 assessment process is complete, clinicians must interpret the results, provide extension testing to test the limits of the student's performance, and synthesize and report all assessment information (Wiig et al. 2013b).

Historical Background

The original CELF was published in 1980 by Eleanor Messing Semel. Since its initial publication, the CELF has undergone four revisions. It was originally developed to identify language disabilities, provide diagnostic information, and identify relative strengths and weaknesses in order to establish priorities for treatment and follow-up intervention. The CELF-3, the second revision to the CELF, was frequently used to evaluate individuals who had suffered traumatic brain injuries (TBI) (Semel et al. 1995; Paslawski 2005). In 2003, the CELF-4 (Semel et al. 2003) was published. It was primarily used to screen for and diagnose language disorders in children and young adults aged 5–21. The norms of the CELF-4 were updated based on a diverse standardization using a US sample of 2,650 individuals that reflected the 2000 US census. Of this sample, 39% identified as minorities and 10% reported having a disability (Wiig et al. 2013b). The CELF-4 was designed as a tool for the clinical decision-making process, including making a diagnosis, determining the severity of a language disorder, identifying relative strengths and weaknesses, making recommendations regarding accommodations and intervention, and measuring the efficacy of intervention (Paslawski 2005).

Additionally, in 2004, the CELF-Preschool, second edition was developed to (CELF Preschool-2) assesses language ability in children ages 3–6 (Wiig et al. 2004; Paslawski 2005). Similar to the CELF-4, the CELF Preschool-2 was used to identify and diagnose language deficits in children and for the purposes of follow-up. The CELF Preschool-2 has four levels of assessment with respect to language disorders, including identification of a language disorder, description of the disorder, assessing the effect of the disorder on classroom functioning, and pragmatics. The

CELF Preschool-2 also overlaps with the CELF-4 for children ages 5 and 6.

Psychometric Data

Standardization for the CELF-5 occurred in 2012, using a sample of 3,250 English-speaking individuals in the USA between the ages of 5 and 21. Participants were gathered from 47 states (Wiig et al. 2013) and were stratified according to age, race/ethnicity (White, Hispanic, African American, Asian, and Other), geographical region (West, Midwest, Northeast, and South), and parent/caregiver education level (less than a high school diploma, high school diploma, some college or technical school, and 4 or more years of college) (Wiig et al. 2013a). Five percent of participants reported having an attention disorder; 1% a learning disability, intellectual disability, pervasive developmental disorder, Down syndrome, or developmental delay; and less than 1% reported having an emotional disturbance, cerebral palsy, color blindness, central auditory processing disorder, visual impairment, autism, or other diagnoses. Approximately 7% were diagnosed with a speech and/or language disorder, 4% with articulation or phonological disorder, and <1% with fluency/voice disorder (Wiig et al. 2013a).

Internal consistency of the CELF-5 was measured using the split-half method with the Spearman–Brown correction formula (Wiig et al. 2013). The average subtest reliability coefficients ranged from acceptable (0.77) to excellent (0.99) for ages 5:0–8:11, while the reliability coefficients for the indexes were excellent and ranged from 0.93 to 0.97. For individuals between the ages of 9:0–21:11, the average subtest reliability coefficients were acceptable (0.60) to excellent (0.99), while the reliability coefficients for the indexes were excellent and ranged from 0.92 to 0.97. Internal consistency was also calculated for individuals from three special populations: language disorders, autism spectrum disorder, and reading and/or writing learning disability (Wiig et al. 2013a). Coefficients for these groups ranged from acceptable (0.75) to excellent (0.99) for the

subtests. Index coefficients were not reported (Wiig et al. 2013a).

Test–retest stability was obtained via Pearson’s product–moment correlation by administering the CELF-5 twice within a 7–46-day interval to 137 participants (Wiig et al. 2013a). Participants were grouped in three age groups (5:0–6:11, 8:0–9:11, and 12:0–16:11). Results for the 5:0–6:11 age group indicated acceptable (0.68) to excellent (0.92) subtest stability and good (0.84–0.89) composite stability (Wiig et al. 2013a). Similarly, results for the 8:0–9:11 age group indicated adequate (0.77) to good (0.89) subtest stability and good (0.87) to excellent (0.92) composite stability. Lastly, results for the 12:0–16:11 age group indicated poor (0.56) to excellent (0.93) subtest stability and good (0.86) to excellent (0.91) composite stability (Wiig et al. 2013a).

The majority of subtests on the CELF-5 are objectively scored (i.e., correct or incorrect), thus they were not analyzed for interrater reliability. However, the following subtests require qualitative judgment for scoring of responses: Word Structure, Formulated Sentences, Word Definitions, and Structured Writing. Overall interrater reliability for these subtests was excellent and ranged from 0.91 (Formulated Sentences) to 0.99 (Word Structure) (Wiig et al. 2013a).

Furthermore, good to strong interrelationships among all subtests and composites support the validity of the CELF-5. Intercorrelations ranged from 0.19 to 0.65 for subtests and from 0.72 to 0.97 for composites. Additionally, the relationship among scores on the CELF-5 and other measures of language development informed the measure’s concurrent validity (Wiig et al. 2013a). Correlations between CELF-5 and CELF-4 subtests were adequate (0.64) to good (0.88), whereas correlations between the indexes were good (0.82) to excellent (0.92). Additional comparisons were made with the Peabody Picture Vocabulary Test–Fourth Edition (PPVT-4; Dunn and Dunn 2007) and the Expressive Vocabulary Test–Second Edition (EVT-2; Williams 2007). The PPVT-4 indicated adequate (0.75) to excellent (0.95) correlations with CELF-5 subtests and adequate (0.68) to good (0.80) correlations with CELF-5

indexes. Similarly, comparisons with the EVT-2 indicated adequate (0.71) to excellent (0.98) correlations with CELF-5 subtests and adequate (0.65–0.78) correlations with CELF-5 indexes (Wiig et al. 2013a).

Clinical Uses

The CELF-5 is a comprehensive assessment that is sensitive to cultural and linguistic diversity and addresses components within the World Health Organization’s International Classification of Functioning, Disability, and Health (2001) (Wiig et al. 2013b). This assessment tool has been developed to aide in the identification of reading and writing difficulties as well as to determine problems with spoken language and the possible impact it may have on a student’s written language. Therefore, the CELF-5 assists clinicians in evaluating a student’s strengths and weaknesses, communicating a student’s needs, addressing parent and teacher concerns, better identifying deficits in social language skills, and identifying the need for an Individualized Education Program (IEP) (Wiig et al. 2013b).

Overall, the CELF-5 allows clinicians to evaluate a student’s general language ability and obtain information that aids in determining if a student has a language disorder by administering four to six tests. Once a language disorder has been determined, the assessment process can be extended in order to further investigate areas of strength and weaknesses. Clinicians are able to determine whether significant differences exist between comprehension and expression, identify weaknesses in the areas of morphology and syntax or semantics, identify how the oral language disorder might affect a student’s written language skills, and examine if the identified language disorder affects the student’s social language interactions.

Center-Based Programs

Sandra Harris

Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey,
New Brunswick, NJ, USA

Definition

Center-based programs for children, adolescents, and adults with autism spectrum disorders (ASD) typically focus their interventions exclusively on this population of learners and are often based in universities although some are freestanding private programs. Center-based programs include research on intervention with ASD as an important aspect of their work.

Historical Background

In the late 1960s, shortly after Lovaas et al. (1965, 1973) demonstrated that children with autism living on a hospital's inpatient unit could learn adaptive skills, interest in the science of applied behavior analysis (ABA) as a treatment approach for autism increased in universities around the United States. For example, the Koegel Autism Center at UC, Santa Barbara, was opened in 1971 with an outpatient clinic and an experimental classroom. The research on pivotal response treatment coming from that center over the years has been highly influential to the field of ABA (e.g., Koegel et al. 1987).

The Douglass Developmental Disabilities Center opened in 1972 at Rutgers University in New Jersey as a research-based day program for school-age children with autism (Harris and Handleman 2000). That program is noted for research on teaching parents to use ABA methods (Harris 1983), for research on the assessment of children with ASD (e.g., Delmolino 2006), and for developing new ABA methods to teach skill acquisition and behavior management (e.g., Jennett et al. 2007). In 1975, Raymond Romanczyk established the Institute for Child Development at the State University of NY at Binghamton. The work on computer-based curricula coming from that center has been adopted in many places (Romanczyk and Lockshin 1982). The Walden Early Childhood program was opened on the campus of University of Massachusetts in 1985 and has since relocated to the Emory University School of Medicine (McGee et al. 2001). Their emphasis on incidental teaching with preschool-age children has had an important impact on preschool programs for children with ASD (McGee et al. 1999).

Not all centers are university based. For example, the Princeton Child Development Institute in New Jersey (McClannahan and Krantz 2001) is a freestanding private program that has an affiliation with the University of Kansas but is physically far removed from that campus. They have made major contributions to the understanding of the treatment of ASD including a competency-based staff training program and the use of

activity schedules to help students with ASD function independently (McClannahan and Krantz 1999). Another freestanding program located in New Jersey that has a research focus is the Alpine Learning Group which was founded in 1989 and contributes research findings in several areas of ABA (e.g., Meyer et al. 2000).

Rationale or Underlying Theory

Many center-based programs are at universities in which innovative research in the treatment of autism spectrum disorders can most efficiently be done, and others are private programs that place a high value on doing research as part of their mission. Once new ABA teaching techniques have been developed in these environments, they are fine-tuned to work in school-based and home-based settings. Instructional methods developed in research settings have very limited value if they can only be applied in the center where they were created. It is essential that the methods be shown to be effective when used by well-trained staff members in community settings as well. The Princeton Child Development Institute, for example, has consulted to several replication sites that adopted their approach. These sites are located in College Point, NY; New Milford, NJ; Bedminster, NJ; Maplewood, NJ; Gdansk, Poland; and Istanbul, Turkey.

Goals and Objectives

One goal of center-based programs is to develop effective treatments for learners with an autism spectrum disorder (ASD). For university-based programs, another goal is teaching undergraduate and graduate students how to implement these methods. After they leave the university, these students can bring the ABA treatment methods into the wider community and help disseminate cutting-edge techniques in public and private schools. Some center-based programs have staff members who consult to schools and families about the most effective ways to educate students with ASD and share their knowledge through that consultation.

There are significant advantages to providing treatment in a center-based program. One of these is that the entire staff is focused on the treatment of ASD, and this depth of talent ensures that if a teacher is on jury duty or an assistant teacher is on medical leave, there will be other experienced staff members able to step in and maintain a high-quality program for a learner. Public schools rarely have the resources to ensure that kind of coverage, and parents running their own home-based program may find themselves overwhelmed when there are not enough staff members to cover the teaching hours in the day. Another advantage is that center-based programs typically use cutting-edge teaching methods. These data-based methods offer the learner a major advantage in terms of the likelihood of making progress over time.

One potential disadvantage of a center-based program is that there may not be easy access to typically developing peers. By contrast, the public schools are primarily comprised of youngsters in regular education classes who can be invited to serve as role models. To compensate for the lack of neurotypical peers, some center-based programs, especially at the preschool level, include a classroom of typically developing preschool children who can be role models and friends for young children with ASD. This provides an inclusive experience for the child who is getting ready to go to kindergarten in a public school. In addition, when children in a center-based program are ready to be transitioned to their home districts, they will make many visits over an extended period of time to help them feel comfortable when they are fully included in the public school. This transition process allows the center-based staff to identify skill deficits that need to be addressed for the child to fit into the new placement. Older learners who still require intensive services of a center-based program often spend significant amounts of time in community settings where they are exposed to children or adults of their own age.

The extent of parental control varies by instructional setting. In home-based programs, parents are typically present for much of the instructional time and are active in making day-by-day decisions. Some parents value this role and expect to

be very active in their young child's education. However, in families where both parents must work or in single-parent families, it is not feasible for parents to be at home overseeing the teaching programs and still earn a living to support their family. Under these conditions, a center-based program or a school-based program has the advantage of allowing parents to leave much of the daily decision-making to the educational team. By law, parents must have a voice in planning their child's education, but when the program is not home based, they do not have the intensive control of daily decision-making that is possible in their own home.

Treatment Participants

Children of all ages, adolescents, and adults may be served by center-based programs. The centers vary in how they select learners. They may recruit students with specific educational needs, for example, significant speech delays or problems with forming important visual or auditory discriminations, to test a new intervention. Alternatively they may admit students who cannot be accommodated in the public schools because of the complexity of their learning needs, the lack of trained staff with a knowledge of ASD in the district, or seriously challenging behaviors on the part of the learner. Although inclusion in a regular education class is a goal for every child, there are some learners with autism spectrum disorders whose behavioral challenges make that goal difficult, if not impossible, to achieve.

Treatment Procedures

Many center-based programs are at universities with a commitment to developing empirically supported treatments, and others are private programs which share that research goal. Because applied behavior analysis (ABA) has the best track record of providing rigorous evidence, most center-based programs employ a broad array of ABA methods. They range from naturalistic teaching in a playful setting with a young

child or helping a teenager with ASD take public transportation to using more structured methods including discrete trial teaching to help students learn factual knowledge that forms the basis for effective communication and improved cognitive skills. Among the many behaviors that children with ASD have learned with ABA techniques are empathy skills (Schrandt et al. 2009), using a greater diversity of responses (Napolitano et al. 2010), and requesting answers to novel questions (Ingvarsson and Hollobaugh 2010). Rogers and Dawson (2010) have developed ABA techniques that are developmentally informed to work with very young children starting at 1 year of age and continuing to age 5 years.

For difficult-to-manage behavior such as self-injury, aggression, or tantrums, ABA offers sophisticated functional assessment/analysis techniques followed by the development of a treatment intervention to teach the student positive alternatives to disruptive behavior (e.g., Hanley et al. 2003). For example, a child who is motivated to slide to the floor because it gains her teacher's attention might learn to raise her hand or give the teacher a card that says "Talk to me please." Similarly, a teenager who is motivated to avoid a task might learn to ask for a "break please" or give the teacher a "break card."

Efficacy Information

As reflected in this encyclopedia, there is a substantial body of empirical data demonstrating that techniques based on the principles of ABA can be highly effective in teaching new skills in multiple domains including communication, social behavior, adaptive behaviors, vocational skills, and the self-control of maladaptive behaviors. Much of this research comes from center-based programs (e.g., Charania et al. 2010; Koegel et al. 1997; Miguel et al. 2009).

Outcome Measurement

Starting with the pioneering work of Lovaas, much of the published outcome research has

evaluated home-based treatment. Center-based research often results in research articles focused on changes in specific behaviors. For example, R. L. Koegel and L. K. Koegel (Koegel and Koegel 2006) use single-subject designs to illustrate changes in communication and social and academic skills when children are taught skills using pivotal response treatments. Single-subject designs include a multiple baseline design across individuals where two or more people have baseline (untrained) data collected on a target behavior and then one person enters treatment while the others continue in baseline. When the first person reaches criterion, the next person enters treatment and so forth. Multiple baseline designs can also be used for one participant across three or more tasks.

Another single-subject design is called a reversal design, and in using this intervention, baseline data are first collected, then the treatment is introduced, and after changes have been observed, there is return to baseline for a brief period, and finally the treatment, if demonstrated to be effective, is put in place. Single-subject designs are especially useful for the in-depth study of the influence of teaching methods on individual participants.

In addition to single-subject designs, some longer-term follow-up studies of the effectiveness of ABA treatments employ group designs in which participants are assigned randomly to different conditions including a treatment group and a group that receives the usual services available in the community (called treatment as usual, TAU). Data from these studies are analyzed using statistical methods to compare differences between groups (e.g., Harris and Handleman 2000; Rogers and Dawson 2010; Sallows and Graupner 2005; Smith et al. 2000).

Qualifications of Treatment Providers

Treatment providers in many center-based programs include assistant teachers with high school diplomas or who are university undergraduates. They are supervised by special education teachers

who have, or are working toward, their board certification as behavior analysts. Some center-based programs also have speech and language therapists who, in addition to their speech credentials, hold the BCBA certificate. Senior supervisors typically have the BCBA credential, have many years of experience, and are often faculty members engaged in research and staff training. This creates an environment that can be quite dynamic in ensuring that services remain state of the art.

Central Auditory Processing Disorder

Shannon Palmer

Central Michigan University, Mount Pleasant, MI, USA

Synonyms

Auditory perceptual disorder; Auditory processing disorder

Short Description or Definition

A central auditory processing disorder (CAPD) is defined as difficulty with “processing auditory information in the central nervous system and neurobiological activity that underlies and gives rise to the electrophysiologic auditory potentials” (American Academy of Audiology [AAA] 2010). This processing difficulty results in poor performance in localization and lateralization, auditory discrimination, auditory pattern perception, and temporal processing (American Speech-Language-Hearing Association [ASHA] 2005). Individuals diagnosed with CAPD often exhibit trouble following oral instructions, difficulty in background noise, problems with reading, spelling and language, and academic difficulties (Bamiou et al. 2001; Chermak et al. 2002).

Categorization

Currently, there is no consensus on the categorization of CAPD. There are two proposed models of CAPD in children: the Buffalo model (Katz 1992) and the Bellis-Ferre model (Bellis 2003; Ferre 1997). Both of these models attempt to categorize CAPD based on the types of difficulty the individual exhibits. However, neither of these models is based on peer reviewed data, and neither model is able to categorize all children diagnosed with CAPD (Jutras et al. 2007).

Epidemiology

The epidemiology of CAPD is not well documented at this point in time. There is one estimate that 2–3% of children have an auditory processing disorder (Chermak and Musiek 1997). In adults, it is estimated that 10–20% of elderly adults demonstrate an auditory processing disorder (Cooper and Gates 1991).

Natural History, Prognostic Factors, Outcomes

There are no longitudinal studies following individuals with CAPD, therefore, prognostic factors and outcomes cannot be estimated at this point in time. Some risk factors for CAPD have been identified, including neurological dysfunction or disorders, severe jaundice during infancy, chronic otitis media during preschool years, and family history of CAPD, hearing loss, or academic underachievement.

Clinical Expression and Pathophysiology

For most children with CAPD, the exact cause of the disorder is unknown. However, inefficient interhemispheric information transfer and imprecise neural synchrony, among other things, may be involved (Jerger et al. 2002). Neurological disorders, damage, or abnormalities may also be the cause of CAPD if the auditory areas of the brain are affected (Musiek et al. 1994).

Evaluation and Differential Diagnosis

Currently, there is no gold standard test for evaluating and diagnosing auditory processing disorders. Rather, as the definition of CAPD includes disorders of multiple auditory skills, the evaluation of CAPD should also include tests of multiple auditory skills (AAA 2010; ASHA 2005). This is done using a test battery approach. A typical CAPD evaluation will begin with a test of hearing sensitivity to rule out any type of peripheral

hearing loss. Individuals exhibit difficulty with one or more auditory functions as a result of poor processing of auditory information beyond the ear. This represents a problem with the auditory system beyond the inner ear. Therefore, an individual who is seeking a diagnosis of CAPD should not have peripheral hearing loss on a pure tone audiogram test. The current recommendations from the American Academy of Audiology state that a diagnosis of CAPD should be given if a person performs below the age-established norms on two or more tests of central auditory function (AAA 2010). Tests that may be included in a CAPD test battery can be divided into two main categories: behavioral tests and electrophysiological tests.

Behavioral tests are designed to assess one of the many areas of auditory processing. These tests require individuals to participate in the testing process in some way. This includes pressing a button, raising their hand, or repeating what they hear. The main processes evaluated by behavioral tests are binaural integration, binaural separation, auditory closure, temporal resolution, temporal ordering, and understanding speech in noise. Some tests currently available to evaluate binaural integration include the Dichotic Digits Test, Staggered Spondaic Words Test, and the binaural integration subtest of the SCAN (Katz et al. 1963; Keith 2000a; Musiek 1983). These tests involve having different information presented to the left and right ear simultaneously (dichotic testing). Individuals are asked to listen to what is being presented to both ears and repeat back everything they hear. Binaural separation is also tested using a dichotic test procedure; however, they are asked to focus on the sounds presented to one ear while ignoring what they hear in the other ear. Some tests of binaural separation include the competing words and competing sentences subtests of the SCAN and the competing sentences test (Keith 2000a). Auditory closure is the brain's ability to fill in missing information. This is tested by presenting words or sentences that have had some information removed and asking individuals to repeat what they hear. Some examples of auditory closure tests include low-pass filtered speech and compressed speech.

Temporal processing is related to the timing aspects of sound. Temporal resolution is the ability to hear changes in a sound over time (Moore 2003). This is often evaluated using a gap detection task, in which individuals are asked to press a button when they hear a small piece of silence embedded in static noise. Clinically applicable tests of temporal resolution include the Gaps in Noise (GIN) Test (Musiek et al. 2005) and the Random Gap Detection Test (Keith 2000b). Temporal ordering is the skill of determining the order in which multiple stimuli were presented. This is evaluated by presenting two to three sounds that vary in some aspect (frequency or duration) and asking individuals to report in what order they heard the sounds. These tests are the Frequency Pattern Test and the Duration Pattern Test (Musiek 1994).

Because one of the most common complaints of someone with CAPD is difficulty understanding speech in the presence of background noise, many CAPD test batteries include a speech in noise test. These tests present words or sentences with some type of background noise. This noise may be broadband or multi-talker babble. The difference in loudness between the signal that the individual must repeat (words or noise), and the background noise may vary. Some of these tests include the Words in Noise (WIN) test, the QuickSIN, the Hearing in Noise Test (HINT), and the Speech Perception in Noise (SPIN) Test.

The difficulty with all of these CAPD tests for use with individuals diagnosed with autism is that they require the individual to actively and cooperatively participate in the test procedures. These tests also use varying amounts of speech materials for testing and/or instruction. This requires each individual tested to have normal or near normal speech and language abilities and normal cognitive function in order to complete the tests. These requirements would disqualify most individuals with autism from being able to reliably complete the test procedures. Therefore, testing and diagnosis of CAPD is not typically done on individuals with autism.

Electrophysiological (evoked potential) tests involve placing small recording electrodes on the surface of the scalp, forehead, and ears. For this

type of testing, the individual is asked to sit quietly while listening to various sounds. The electrodes record responses from groups of neurons in the brainstem and brain when a sound is presented. Individuals with CAPD may have abnormalities in the size or timing of their evoked potentials responses. Some studies have also found abnormalities on some electrophysiological tests of individuals with autism, although the research findings tend to be mixed (Marco et al. 2011). These tests allow the evaluation of the function of auditory areas of the central nervous system without active participation on the part of the individual. However, electrophysiological tests alone cannot diagnose CAPD. The results of these tests should be combined with behavioral test measures to diagnose CAPD.

Treatment

Treatment options for CAPD fall into four general categories: environmental modifications, informal auditory training, formal auditory training, and computer-based training. Environmental modifications are designed to improve the signal-to-noise ratio (SNR) for the child with CAPD. SNR is the intensity of the signal the listener is meant to attend compared to the intensity of the background noise that should be ignored. Some of these modifications may include offering preferential seating in the classroom, reducing background noise, providing written instructions for assignments and projects, previewing or pre-teaching classroom materials, and some form of assistive listening technology. The goal of these strategies is to improve the individual's functioning in difficult listening situations, not to remediate the CAPD directly.

Informal auditory training and formal auditory training are activities created for each individual that are designed to improve the specific auditory skills with which the child has difficulty. These activities are either completed at home (informal training) or during scheduled rehabilitation sessions (formal training) with a speech-language pathologist or audiologist. The exact activities will be individualized for each individual and

may include auditory skills similar to those used during the test procedures. These activities begin with easier tasks and progress to more difficult assignments.

Cerebellar Abnormalities in Autism

Antonio Y. Hardan¹ and Roger J. Jou²

¹Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, USA

²Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Definition

Cerebellar abnormalities consist of some of the earliest neurobiological findings to be described in autism spectrum disorders (ASD). Like other brain anomalies reported in this disorder, cerebellar abnormalities are diverse with varying levels of inconsistency and specificity. Therefore, the contribution of the cerebellum to the pathophysiology of ASD remains unclear. Nevertheless, this structure continues to be of great interest to the autism research community in light of growing evidence suggesting a role that goes beyond motor coordination (see entry: ► [“Cerebellum”](#)). More precisely, recent research has provided clear evidence supporting the involvement of the cerebellum in emotion processing and cognition (Schmahmann and Sherman 1998) which are commonly impaired in individuals with ASD.

This entry briefly summarizes the research literature on the cerebellum as it applies to ASD. Ovid MEDLINE search of the entire medical literature (1948–2010) revealed that this covers approximately 25 years of research. The earliest studies (1985–1999) are briefly summarized in the [“Historical Background”](#) section as there are already many published reviews on this earlier work. In the [“Current Knowledge”](#) section, a more detailed review is provided on research published in the past decade which consists of the majority of published work on cerebellar abnormalities in ASD.

Historical Background

The earliest studies describing cerebellar abnormalities in ASD were published in the mid-1980s. These studies were of two general types: neuropathology and structural neuroimaging. The first neuropathological investigations consisted of case reports or series which reported (Frazier and Hardan 2009) various cerebellar abnormalities, including the well-known finding of decreased Purkinje cell number (Bauman and Kemper 1985; Ritvo et al. 1986) which are distinctive inhibitory output neurons arising from the cerebellar cortex (see entry: ► [“Purkinje Cells”](#)). This finding was replicated a decade later by another group using a different sample, reporting Purkinje cells reduction in postmortem cerebellar tissue (Bailey et al. 1998). These initial neuropathological reports implicating the cerebellum sparked a large number of confirmatory studies with structural MRI being the most commonly used modality. These investigations produced mixed results with respect to cerebellum size and one of its major subdivisions, the vermis, which includes 10 lobules (i.e., anterior vermis, lobules I–V; posterior superior vermis, lobules VI–VII; and posterior inferior vermis, lobules VIII–X). Some reports described smaller cerebellar vermis (Courchesne et al. 1988) while others found normal (Garber and Ritvo 1992) or even larger size (Piven et al. 1997). It should be noted, however, that the initial MRI studies had significant limitations, partially owing to the novelty of this technology in neuropsychiatric research during this time period. For example, many studies reporting on size of the cerebellum refer to area as measured in midsagittal slices and not volume. Finally, a series of studies using clinical assessments to indirectly test for underlying cerebellar neuropathology were also published in the 1980s and 1990s. These investigations assessed a number of abilities believed to depend on the cerebellum, including gait (Hallett et al. 1993), attention (Courchesne et al. 1994), and eye movements (Minshew et al. 1999). These findings were also mixed, though most reports cited abnormalities suggestive of cerebellar pathology.

Current Knowledge

In the past decade, there has been a surge in the number of autism-related published studies. This large body of research was accompanied by major technological advances which enabled clinicians/scientists to study new questions and clarify existing ones. These advances have led to an increase in our understanding of the role of the cerebellum in ASD; however, there is still much to be learned. Inconsistent findings remain a challenge, and the implications of new findings are not entirely clear and/or need replication. This portion of the review is organized by research modality which includes the following: neuropathology, molecular/cellular neurobiology, neuroimaging, and clinical testing. The neuroimaging literature represents the majority of the published work, and this section will be divided further by imaging modality.

Neuropathology

While some of the most informative research has come from postmortem neuropathological examination, this group of studies continues to represent only a small minority of autism-related published studies. Nevertheless, recent research has provided new and informative insights. The well-known observation of reduced Purkinje cell counts was reported to be an inconsistent finding and may only be found in a subpopulation of individuals with ASD (Whitney et al. 2008). Moreover, in a recent neuropathological study, cerebellar pathology was commonly observed, but reduction in Purkinje cells was not consistently found (Wegiel et al. 2010). However, this does not necessarily diminish the importance of Purkinje cells as part of the neuropathology of ASD. Abnormalities in this population of cells may be expressed in other ways such as size reduction which has also been reported (Fatemi et al. 2002). In addition to Purkinje cells, basket and stellate cells (key cerebellar inhibitory interneurons) have been studied, and no abnormalities have been observed in their number or shape, suggesting that Purkinje cell loss is related to a late developmental event (Whitney et al. 2009).

Molecular/Cellular Neurobiology

This category includes human experiments done on the molecular and cellular level, usually involving the use of postmortem neural tissue or blood serum from living participants. As a broad category, these studies represent much of the research in ASD reporting on cerebellar anomalies; however, this grouping is quite diverse and represents mainly preliminary work which needs replication and further investigation. Nevertheless, the resulting research has provided significant leads into the molecular basis of ASD. One way to conceptualize this body of literature is by predicted aberrations in the following: neurotransmission, immune function, apoptosis (programmed cell death), and cell signaling. With respect to neurotransmission, abnormalities have been reported in the gamma-aminobutyric acid (GABA), nicotine, and glutamate neurotransmitter systems. There are now many studies reporting abnormalities in the GABAergic system which mainly includes abnormal expression of GABA receptors (Fatemi et al. 2009) and the rate-limiting, GABA-synthesizing enzyme, glutamic acid decarboxylase (Fatemi et al. 2002; Yip et al. 2007). Studies have also been published, although limited in number, to support abnormalities in the nicotinic (Lee et al. 2002) and glutaminergic systems (Purcell et al. 2001).

Immune dysfunction has also been implicated as part of the pathobiology of ASD. There are several studies reporting on the presence of antibodies to cerebellar proteins in the serum of individuals with ASD (Singer et al. 2006; Wills et al. 2009). A recent investigation specifically identified a neuroinflammatory process in postmortem cerebellum tissue of individuals with ASD (Vargas et al. 2005) which was subsequently supported by a similar study (Laurence and Fatemi 2005). Additionally, there are also several studies that support the presence of aberrant apoptosis in the cerebellum of individuals with ASD. These investigations reported the reduction of antiapoptotic protein Bcl-2 (Fatemi et al. 2001) and increase in proapoptotic proteins, cathepsin D and caspase-3 (Sheikh et al. 2010). Finally, many studies have found

abnormal levels of one or more of the numerous proteins involved in various cell signaling processes. Those proteins found to be abnormal in the cerebellum of individuals with ASD include reelin (Fatemi et al. 2005), phosphodiesterase (Braun et al. 2007), and neurotrophin-3 (Sajdel-Sulkowska et al. 2009).

Neuroimaging

Structural MRI

Structural MRI is one of the most commonly used neuroimaging modalities to study the neurobiology of ASD (see entry: ► [“Magnetic Resonance Imaging”](#)). Major advances in recent structural MRI methodologies or technologies include the use of novel semiautomatic morphometric software that led to improved ability to perform volumetric measurements and separately measure gray and white matter volumes. These new software programs allow the examination of increasingly larger sample sizes, enhancing statistical power and facilitating important group stratification (i.e., by age, gender, etc.). However, the inconsistencies present in the earlier structural MRI literature persisted in the newer studies. In fact, the results have become even more mixed. There are several reports documenting increases in cerebellar size, including total volume (Hardan et al. 2001), gray matter (Ke et al. 2008), white matter (Bloss and Courchesne 2007), and/or vermal lobules (Akshoomoff et al. 2004). In contrast, findings from several other studies revealed reductions in cerebellar size, including total volume (Hallahan et al. 2009), gray matter (Toal et al. 2010), white matter (Courchesne et al. 2001), and vermal lobules (Carper and Courchesne 2000). Finally, reports documenting normal cerebellar volumes have also been published (Hazlett et al. 2005). It is worth noting that most of these newer studies do not restrict their analysis to the cerebellum, and most conduct a whole-brain analysis also reporting on extracerebellar anomalies while examining different age groups. Therefore, future studies should focus on the cerebellum solely while including a large sample of participants and a narrow age range.

Functional MRI

Functional MRI studies are also among the most commonly used neuroimaging modality to study the neurobiology of ASD (see entries: ► [“Functional MRI”](#), and ► [“Magnetic Resonance Imaging”](#)). While some studies reported on the cerebellum in their analyses, a limited number of investigations focused primarily on this structure. Studies have applied motor tasks and paradigms, probing cognitive and emotional processing (Schmahmann and Sherman 1998). Motor tasks commonly involved finger tapping or button pressing, and some investigations have reported reduced (Mostofsky et al. 2009; Muller et al. 2001) while others found increased cerebellar activation (Allen and Courchesne 2003; Allen et al. 2004) in individuals with ASD when compared to controls. Abnormal cerebellar activation has also been reported in nonmotor probes of attention (Allen and Courchesne 2003), executive function (Gilbert et al. 2008), and face processing (Critchley et al. 2000). Abnormalities of how the cerebellum connects to other brain areas have also been observed in a recent investigation examining functional connectivity with evidence indicating a lack of synchronization between this structure and several brain regions during task performance (Belmonte et al. 2010; Mostofsky et al. 2009). Finally, decreased cerebellar activation has been demonstrated in studies examining resting state activity where no tasks are used (Paakki et al. 2010).

Other Neuroimaging Modalities

The remaining neuroimaging modalities, diffusion tensor imaging, magnetic resonance spectroscopy, and single-photon emission computed tomography, are less commonly used (see entries: ► [“Magnetic Resonance Spectroscopy”](#), and ► [“Magnetic Resonance Imaging”](#)). Diffusion tensor imaging has grown tremendously in popularity over the past 5 years, and there are now more than 30 published studies conducted in autism research. However, only a minority of these investigations reported cerebellar abnormalities including impaired white matter integrity as measured by fractional anisotropy. These abnormalities are found in the middle (Cheng et al.

2010) and superior cerebellar peduncles (Catani et al. 2008) which are the major fiber tracts going into and coming out of the cerebellum, respectively.

Most magnetic resonance spectroscopy studies, but not all (Endo et al. 2007), have also described abnormal cerebellar metabolite levels in ASD. Increased myoinositol and choline levels have been observed (Gabis et al. 2008), as well as decreased N-acetylaspartate and glutamate + glutamine (DeVito et al. 2007). These metabolites reflect different functions with myoinositol being essential for cell growth, choline being considered as a measure of membrane synthesis and turnover, N-acetylaspartate as a putative marker of neuronal viability, and glutamate + glutamine being related to excitatory pathways (see entry: ► [“Magnetic Resonance Spectroscopy”](#)). Finally, there is one study using single-photon emission computed tomography which did not find any significant differences in the cerebellum (Hashimoto et al. 2000).

Clinical Testing

Thus far, this review has focused on studies making direct assessments of the cerebellum via imaging or postmortem tissue. An indirect way to assess cerebellar abnormalities is through clinical evaluation. This is analogous to a neurologist determining the location of a stroke by examining the pattern of neurological impairments and clinical symptoms. Many different assessments have been used, and the choice depends on the system or brain region that is being tested. For the cerebellum, motor and nonmotor deficits are usually evaluated. Most, but not all, investigations probing the former have reported alterations suggestive of cerebellar pathology (Goldberg et al. 2000). Specifically, abnormalities have been reported in postural control (Dowell et al. 2009; Minshew et al. 2004), gait (Rinehart et al. 2006), eye movements (Takarae et al. 2004), and hand-eye coordination (Gowen and Miall 2005). Similarly, probing various cognitive functions, thought to depend on cerebellar integrity, have also yielded evidence of alterations in perceptual abilities (Davis et al. 2006) and learning (Mostofsky et al. 2000).

Future Directions

The investigations reviewed here support the integral role that the cerebellum plays in the pathophysiology of ASD. However, the exact involvement of this structure in the development of this disorder remains unclear despite 25 years of intensive research. From the information discussed above, the prevailing evidence in the field is that cerebellar abnormalities do not occur in isolation and do not appear to be specific to ASD. Nevertheless, it remains an important goal to continue investigating the contribution of the cerebellum to the clinical and biological abnormalities observed in ASD. Studies should be comprehensive, applying multimodal imaging and biological techniques, to increase both our general understanding of the cerebellum and the role it plays in autism.

Definition

The cerebellum is a major division of the brain located in the posterior fossa behind the brainstem and underneath the cerebrum. It is attached or connected via three pairs of large fiber bundles (superior, middle, and inferior cerebellar peduncles) and is subdivided by two transverse fissures into three lobes (flocculonodular, anterior, and posterior lobes). Additionally, the cerebellum is divided into longitudinal zones which cut across the three lobes, resulting in two hemispheres (left and right) which flank a narrow midline zone called the vermis. Cerebellar circuitry has a uniform organization: inputs to the cerebellar cortex arrive through the middle/inferior peduncles. Neurons in the cerebellar cortex project to a series of deep cerebellar nuclei (dentate, interposed, emboliform, and globose nuclei) which provide outputs through the superior peduncle. Traditionally, the cerebellum's primary role is in motor control/learning including mediating equilibrium, postural control, and coordination/planning of voluntary movements. More recently, the cerebellum has been implicated in several cognitive functions including attention, learning, and language, as well as in some emotional functions such as regulating fear and pleasure responses. In general, damage to the midline (vermis) causes instability in posture and gait. Lateral damage (hemispheres) causes abnormalities in the limbs,

including decreased muscle tone, reduced reflexes, abnormal speech, tremor, and incoordination. Deficits in these functions have been reported in autism. However, studies of postural control in autism have linked impaired balance to reduced integration of multisensory information (joint-muscle position sense, visual, and vestibular) and not to cerebellar dysfunction. FMRI studies of motor movements have demonstrated deficits in cerebral connectivity rather than the cerebellum as the basis for coordination impairments in autism. The reduction of Purkinje cell number in the cerebellum has been widely found at autopsy brain examination in autism. Purkinje cells are inhibitory neurons which contain the neurotransmitter gamma-aminobutyric acid (GABA) to modulate neuronal transmission. Oculomotor studies in autism have also demonstrated subtle differences related to posterior fossa circuitry. Their implications for the pathophysiology of autism are unknown.

Definition

The cerebral cortex is the outermost sheet of neural tissue in the brain and plays a critical role in “higher level” cognitive functions, such as perception, attention, memory, language, executive functions, and consciousness.

Anatomical Organization

The most visually apparent features of the human brain are the folds (gyri and sulci), which are necessary products of packing a large cortical sheet into a limited space (i.e., the skull). As such, the folding pattern is most prominent in humans and primates. At the grossest level, the cortex is divided into four lobes: occipital, temporal, parietal, and frontal. At a microscopic scale, the cortex is organized horizontally into up to six layers and vertically into interconnected columns. Based on the thickness of the layers and the predominance of different neuron types, distinct regions of the cortex, called Brodmann’s areas, can be identified under a microscope. The cortex largely consists of cell bodies of neurons, their dendrites, and short range unmyelinated axons, hence the term “gray matter.” Regions of the cortex are connected to one another by myelinated axons that run through the “white matter” underneath the cortex.

Functional Organization

At the grossest functional level, the cortex can be divided into sensory cortex that takes in basic sensory information (auditory, visual, and somatosensory), motor cortex which plans and executes body motions, and association cortex that organizes input from sensory cortex into a unified perceptual world and performs the abstract thought and planning needed to guide the actions of the motor cortex.

Smaller units of function have been reliably localized in human brains using neuropsychological investigations of function after brain injury and in healthy populations using functional magnetic resonance imaging or positron emission tomography. For example, portions of the left

temporal (Wernicke’s area) and frontal cortex (Broca’s area) participate in language function.

Cerebral Palsy

Itxaso Marti

Neuropediatrics, Hospital Universitario Donostia, San Sebastian, Spain

Synonyms

[CP](#); [Little’s disease](#); [Spastic diplegia](#); [Spastic paralysis](#)

Short Description or Definition

Cerebral palsy (CP) describes a group of disorders of the development of movement and posture, causing activity limitation attributed to nonprogressive disturbances that occur in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation,

cognition, communication, perception, and/or behavior and/or by a seizure disorder.

Categorization

Classification can be helpful in understanding the etiology, choosing a treatment, and even knowing the prognosis.

CP is classified by the type of motor impairment and its distribution:

1. Spastic CP:
 1. Spastic diplegia
 2. Spastic quadriplegia
 3. Spastic hemiplegia
2. Dyskinetic and dystonic CP
3. Hypotonic CP

Epidemiology

It is estimated that 2–3 per 1,000 live newborns have CP. Despite improved obstetric conditions, prevalence remains stable in the last decades, probably related to increase survival of premature infants. Prematurity increases the risk of CP. However, half of the cerebral palsy occurs in term infants.

Natural History, Prognostic Factors, and Outcomes

Natural History

By definition, cerebral palsy is secondary to a static lesion in the developing fetal or infant brain. However, the motor symptoms are progressive and they first appear between the ages of 6 months and 2 years, depending on the subtype of CP.

Functionally, with rehabilitation and physical care, these children can acquire new motor milestones during the first decade of life, remaining stable thereafter. A deterioration in walking ability in adulthood would be expected due to pain,

fatigue, or lack of adapted physical activity, but the few studies that have followed CP patients through adulthood report motor stability during this period for one third to half of the patients.

Prognostic Factors and Outcome

The most important prognostic factor is the type of CP. Most children with spastic diplegia or hemiplegia will acquire independent ambulation. The life span in this group is not shortened. However, children with spastic tetraplegia usually will not walk independently, being the prognosis for the dyskinetic group intermediate. Usually, if the child arrives to sit independently for the age of 2 years, he will arrive to walk alone.

For the quadriplegic group, survival is usually low. Most die from malnutrition, infections, or respiratory problems before they reach adolescence. Those having feeding tubes and inability to support their head, the median survival is 17 years.

The presence of mental retardation, a severe degree of disability, poor socialization, overprotection of parents, and denial of the problem of disability negatively affect a good prognosis for independent living in the adult with cerebral palsy.

Clinical Expression and Pathophysiology

Spastic Syndromes

The symptoms are those of the pyramidal syndrome: hypertonia of the affected body region, spasticity, hyperreflexia, and persistence of archaic reflexes. They are also present with difficulty in fine, rapid, and alternating movements. They are usually associated with some degree of dystonia.

Spastic Diplegia

Spastic diplegia is a clinical syndrome with a greater spasticity in legs than arms, seen most commonly in children born prematurely. It is primarily a disorder of developing white matter, and it is nearly always associated with neuropathological and neuroimaging findings of periventricular leukomalacia. Patients with spastic diplegia are

often identified during the first 6–12 months of life with signs of delayed motor development. Associated symptoms may include strabismus, orthopedic deformities, and oromotor dysfunction. There may be some degree of cognitive dysfunction.

Spastic Quadriplegia

Spastic quadriplegia is presented with bilateral spasticity affecting all extremities, with significant limitations in both mobility and hand use. Associated deficits may be more severe, including intellectual disability, seizures, orthopedic deformities including scoliosis and hip dislocation, and visual impairment. Spastic quadriplegia is the result of a broader range of pathological insults, including genetic and developmental brain malformations, severe periventricular leukomalacia, pre- and postnatal infections, asphyxia, and trauma. As with other cerebral palsy syndromes, low birth weight, prematurity, and complicated neonatal course are important risk factors. Delayed motor development in the first year is usually more prominent than in spastic diplegia.

Spastic Hemiplegia

Spastic hemiplegia represents unilateral spasticity, excluding the face. It often affects children at term. It is produced by damage to one hemisphere, such as prenatal strokes or head trauma. Independent ambulation and normal intelligence are commonly seen. There is no greater language impairment if the dominant hemisphere is affected. There is an increased risk of seizures, growth asymmetry, and sensory impairment of the hemiplegic side. Diagnosis is usually evoked by the end of the first year of life.

Dyskinetic-Dystonic

In children with extrapyramidal syndromes, clinical involvement is characteristically greater in the arms than the legs. Extrapyramidal syndromes are often associated with a marked reduction in speech production, but the child may have relatively preserved intelligence. There is usually involvement of basal ganglia (BG): selective necrosis of neurons in the BG, thalamus, reticular formation, and cerebellum. It is typical of term

infants with perinatal injuries: hypoxic-ischemic encephalopathy, hyperbilirubinemia, etc.

It is usually presented with lethargy, hypotonia, and multisystem involvement. Then psychomotor retardation and hypotonia occur, whereas abnormal movements may appear much later, at about 2 years of age.

Hypotonia and Ataxia

These children present with hypotonia with delayed motor milestones. These patients are distinguished by the preservation of strength and reflexes, suggesting a disorder of the upper motor neurons. This is a heterogeneous group of disorders.

Associated Impairments

Although characterized by their motor dysfunction, children with cerebral palsy frequently have other associated impairments.

Intellectual Disability (ID) Present in 50–75% of patients with CP. Usually more severe in patients with spastic quadriplegia.

Epilepsy Present in 30–50% of cases. More frequent if the lesion affects the cerebral cortex: usually in spastic hemiplegia and quadriplegia. In this group, there is a greater prevalence of ID.

Visual Disturbances Strabismus (50%), retinopathy (10%), cortical deficit (10%), and ocular motility disorders.

Digestive Disorders Malnutrition, dysphagia, gastroesophageal reflux, dental anomalies, and constipation.

Orthopedic Disorders Hip subluxation and osteopenia.

Urinary Disorders Incontinence, urgency, enuresis, detrusor dyssynergia, bladder hypertonia, etc.

Evaluation and Differential Diagnosis

Diagnosis usually requires several consecutive explorations: spasticity does not usually appear

until 6 months of age, dyskinetic movements at 18 months, and ataxia at age 2 years.

The initial symptoms are delayed acquisition of motor milestones, altered tone (hyper- or hypotonia), and persistence of archaic reflexes.

Investigations

MRI

- It is recommended in all cases of suspected CP.
- Ninety percent of children with CP have an altered MRI.
- It helps to know the time and etiology of the CP.

Metabolic Investigations

Less than 5% of the cases are secondary to metabolic disease.

Metabolic tests are only indicated in cases where the history is not typical, for example, no typical MRI, family history of consanguinity, and multiorganic symptoms.

Other Investigations

- EEG if suspected seizures
- Ophthalmologic examination
- ENT evaluation
- Orthopedic evaluation

Treatment

Effective management of cerebral palsy requires a team with medical and rehabilitation specialists to provide careful, coordinated treatment to maximize functional capabilities.

Management should aim to achieve maximal potential in all areas of development and to encourage independence. Realistic, functional goals must be set and periodically reevaluated by the rehabilitative team.

Rehabilitative goals will vary from patient to patient depending on the clinical situation, including ease of care, prevention of orthopedic deformity, or facilitating function.

A range of pharmacological agents are used to treat spasticity:

- For localized or segmental spasticity, recommendations support the use of intramuscular botulinum toxin A.
- For generalized spasticity, oral diazepam and tizanidine should be considered for short-term treatment.
- Surgical procedures are common for orthopedic deformities that arise in spastic patients. These operations have advanced from solo, sequential procedures to simultaneous, collective procedures including both soft tissue and bone.
- For children with severe cerebral palsy, refractory to standard interventions, neurosurgical procedures including intrathecal baclofen, selective dorsal rhizotomy, and deep brain stimulation should be considered.

Physical, occupational, and speech therapies are employed as initial therapies or used in conjunction with medical and surgical treatments, focusing on improving the strength and motion of affected muscles. Occupational and physical therapy play a fundamental role in children. Techniques serve to lessen the effects of inhibitory reflexes, to facilitate the acquisition of gross and fine motor skills, and to encourage language and the promotion of confidence and self-esteem.

Synonyms

CSF; Spinal fluid

Definition

Cerebrospinal Fluid (CSF) is a clear, colorless liquid with the consistency of water that fills the ventricular system and subarachnoid spaces around the brain and spinal cord. It is produced primarily by the ependymal cells in the choroid plexus and is absorbed via vesicular transport in the arachnoid villi. The production and absorption of CSF are continuous processes that normally occur at equal rates. These processes lead to the complete replacement of the total volume of CSF approximately three times a day. The circulation of CSF is also continuous. The direction of flow is from the lateral ventricles through the cerebral

aqueduct, out either the foramina of Luschka or the foramen of Magendie, and downward posterior to the spinal cord. It then flows upward, anterior to the spinal cord and over the cerebral cortex.

CSF Composition

The CSF is sampled via lumbar puncture and is assayed to provide information relevant to diagnosis, pathophysiology, and treatment. A blood sample is drawn at the same time as the lumbar puncture in order to compare CSF levels with plasma levels of the elements below. The norms for the following can vary with age from premature infant to adult:

1. Osmolality and solute concentrations – CSF is iso-osmolar to blood plasma with normal CSF osmolality being 289 mOSM/L. The concentrations of sodium, magnesium, and bicarbonate are similar to plasma; however, the concentrations of potassium, calcium, and amino acids are lower in CSF than in plasma.
2. Cells – CSF is rather acellular with the normal density of white blood cells being less than five per high-powered field. Red blood cells are not normally present in the CSF.
3. Glucose – The normal concentration of glucose in CSF is 45–80 mg/dL, approximately two-thirds of the level of the normal serum glucose.
4. Protein – There is a rostral to caudal concentration of protein within the nervous system. The normal concentration of protein in CSF is 15–50 mg/dL.

Additional specific assays are performed depending on the differential diagnosis.

CSF Functions

1. Physical support – The brain and spinal cord essentially “float” in the CSF within the skull and spinal column.
2. Protection – CSF prevents the brain from colliding with the bony skull in cases of head injury. Additionally, the volume of CSF can redistribute in order to maintain normal intracranial pressure when volume changes occur in the other intracranial contents.

3. Metabolism – CSF aids in the excretion, elimination, and transport of centrally acting hormones and brain metabolites.

Relevance of CSF to Autism

A lumbar puncture is not a part of the standard workup or evaluation of children with ASD. Studies of CSF have been pursued in ASD as part of research seeking evidence related to various theories about the pathophysiology of autism. It is important to remember that CSF levels are not necessarily representative of brain levels and certainly not of regional or localized brain levels.

1. Neurotransmitters – There are scattered reports of altered neurotransmitter levels and function, including levels of tetrahydrobiopterin (sapropterin), serotonin, norepinephrine, and dopamine. While pervasive evidence of neurotransmitter abnormalities is lacking, alterations or nutritional deficiencies important for neurotransmitter formation and function (e.g., folate) may account for a very small subset of individuals with ASD (Frye 2010).
2. Mitochondrial disease – Elevated CSF lactate may be an important biomarker for individuals with ASD who have an underlying mitochondrial disease. It is unclear whether mitochondrial dysfunction contributes to the pathogenesis of ASD, or whether this is an epiphenomenon (Palmieri and Persico 2010).
3. Inflammatory markers in CSF – There are limited reports of elevated inflammatory markers in the CSF in individuals with ASD. While immune-based therapy for autism has received recent attention, there is a lack of control data to determine the specificity of this finding (Zimmerman et al. 2005).

Certified Rehabilitation Counselor

Beth Garrison
Hartford Hospital Pain Treatment Center, Bristol,
CT, USA

Synonyms

Canadian Certified Rehabilitation Counselor (CCRC); Certified Rehabilitation Counselor (CRC)

Definition

The Commission on Rehabilitation Counselor Certification (CRCC) sets the standard for quality rehabilitation counseling services in the USA and Canada. It is an independent, not-for-profit

organization. It is this agency that gives the certified designation to a rehabilitation counselor. The CRCC is accredited by the National Commission for Certifying Agencies (NCCA).

According to the Commission on Rehabilitation Counselor Certification (CRCC) agency, this certification designation indicates a “higher level of specialized education and training, a thorough understanding of key competency standards based on current practices in the field, adherence to the Code of Professional Ethics for Rehabilitation Counselors, and an ongoing commitment to continuing education.”

The CRCC mandates that to receive this designation a person must be of good moral character, meet acceptable standards of quality of practice, and have the requisite education and professional background. There are stringent eligibility requirements requiring a minimum of a Masters degree in Counseling or Rehabilitation Counseling together with specified work experience qualifications. The person must take and achieve a passing score on the CRC examination and renew their certification every 5 years via at least 100 h of continuing education or re-examination.

With one exception, Masters and Doctoral degree candidates must have received their education from a program accredited by the Counsel on Rehabilitation Education (CORE) or from a college or university accredited by the Council for Higher Education Accreditation (CHEA). CORE accredits graduate programs which provide academic preparation for a variety of professional rehabilitation counseling positions. CHEA is the largest institutional higher education membership organization in the USA. It is governed by a 20-person board of college and university presidents, institutional representatives, and public members.

If a candidate receives a Masters in Rehabilitation Counseling from a non-CORE program, then they must complete a rehabilitation counseling internship of 600 clock hours supervised by a CRC plus 12 months of acceptable employment experience supervised by a CRC, or 24 months of acceptable employment experience including 12 months supervised by a CRC.

Certification, unlike state licensure, is a voluntary process and is not government regulated. It is

not mandated by any state or federal laws; however, eligibility to sit for the certification exam is federally mandated if a person wishes to work in a state or federal vocational rehabilitation system.

Chaining

Mary Jane Weiss and Samantha Russo
Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Definition

Chaining refers to a variety of procedures for teaching behavior chains. A behavior chain is a series of responses in which each step serves both as a reinforcer for the previous step and as a discriminative stimulus for the next step (e.g., Cooper et al. 2007). The reinforcer delivered at the end of the chain maintains all of the previous responses in the chain.

It is important to teach behavior chains for complex sequences of responses that must be maintained at independent levels. Chaining procedures are used to teach many multistep skills, including self-help and daily living skills. The most common variations of chaining are forward and backward chaining. Task analysis is an essential component of chaining. The determination of steps in a chain that will be taught sequentially is complex and must be done competently.

In forward chaining, the sequence of actions is taught in temporal order. The learner is prompted and taught to perform the first step in the chain; the trainer completes the remaining steps. When the learner masters the first step, he or she is taught to do the first two steps. This continues until the entire chain is taught in sequence independently. Recently, forward chaining has been used to teach specific sequences of component skills in playing a game of basketball (Lambert et al. 2016).

A variation of forward chaining is total task chaining, which is also referred to as whole task or total task presentation. In this variation, the learner receives instruction in every step of the chain in every session. The trainer provides assistance for every step on which it is needed, and training continues until all steps are performed to criterion. Recently, total task chaining has been used to teach hygiene skills to young females with autism spectrum disorder (Veazey et al. 2016).

In backward chaining, the sequence is taught in reverse order, from the completion of the task to the start of the task. At the initiation of training, the trainer completes all but the last step of a chain, which is performed by the learner. Upon completion of this last step, the learner receives reinforcement. When competence is achieved on this final step, the trainer then does all but the last two steps of the chain. To receive reinforcement, the learner must complete the last two steps of the chain. This sequence is continued until the learner completes all steps of the chain independently. Backward chains have been utilized to teach a variety of skills. Recently, backward chaining was utilized to effectively increase functional leisure engagement in children with autism (Edwards et al. 2017). A backward chain is sometimes taught in a modified way, known as leaps ahead. In this variation, some steps may be

skipped if there is sufficient evidence that the learner possesses those components. Allowing skipping of steps increases the efficiency of instruction.

Using a limited hold can target the speed of responding within a chain. In a behavior chain with a limited hold, the sequence of responses must be performed correctly and within a specified period of time. The use of a limited hold targets proficiency in addition to accuracy. This can be used to speed slower responders and to ensure that the individual can engage in the targeted responses in a normative duration.

All chaining procedures are associated with positive results and are effective in teaching skills. There may be individual differences among learners, and an assessment may yield a best choice for that person. Furthermore, it has been suggested that total task presentation may make sense for learners who are more disabled (Test et al. 1990) and who have good imitative repertoires. It may also be a good match for tasks that are not too complex (Miltenberger 2001) and for circumstances in which learners know the steps but need to master them sequentially.

Challenging Behavior

Rebecca DeAquir

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Challenging behavior refers to certain behaviors that a person engages in which negatively affect his/her daily functioning. These behaviors are often recognized as being culturally abnormal and occur at such an intensity, frequency, or duration that the safety of the person and/or others is placed in jeopardy. Challenging behaviors may be related to social, academic, communicative, cognitive, vocational, or physical domains, may serve various functions, and should be examined systematically in order to identify these functions. If challenging behavior is to be decreased, it is important to implement functionally and empirically validated interventions. Common challenging behaviors are self-injurious behavior, aggression, property destruction, stereotypic or repetitive behaviors, and sexualized behaviors.

CHARGE Association

- [CHARGE Syndrome](#)

CHARGE Syndrome

Ellen J. Hoffman

Albert J. Solnit Integrated Training Program, Yale Child Study Center, Program on Neurogenetics, Yale School of Medicine, New Haven, CT, USA

Synonyms

[CHARGE association](#)

Definition

CHARGE syndrome is a rare genetic syndrome (prevalence of 1:3,000–1:12,000) characterized by a constellation of abnormalities, which may include but is not limited to the following: coloboma, or a hole-shaped malformation, of the eye, resulting in visual impairments; heart defects; atresia of the choanae, or blockage of the nasal passages; retardation of growth and development;

genital abnormalities; and ear abnormalities, such as a cup-shaped ear, and deafness (Nussbaum et al. 2007). The co-occurrence of these features was previously referred to as CHARGE association. However, with the identification of the gene responsible for the majority of cases, the term “syndrome” is now preferred (Nussbaum et al. 2007). Additional features of CHARGE syndrome include abnormalities of the cranial nerves leading to deafness, swallowing difficulties, and facial weakness; cleft palate; and fistulae, or abnormal conduits between the trachea and esophagus (Nussbaum et al.). Behavioral difficulties have also been described, such as hyperactivity and obsessive-compulsive behaviors (Nussbaum et al.).

CHARGE syndrome is one of the rare genetic syndromes that has been associated with autism (Filipek 2005). The first report of this association described three children with CHARGE syndrome, two of whom also had intellectual disability, and clinical features of autism, according to the Autism Diagnostic Interview-Revised, Childhood Autism Rating Scale, and the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* (Fernell et al. 1999). The prevalence of autism in CHARGE syndrome has been estimated to be between 15% and 50% (Grafodatskaya et al. 2010). However, the diagnosis of autism in CHARGE syndrome is complicated by the challenge of quantifying social and communication deficits in a syndrome characterized by visual and hearing impairments and, in some cases, intellectual disability as well (Grafodatskaya et al. 2010).

More than half of all individuals with CHARGE syndrome carry mutations in the gene, *chromodomain helicase DNA binding protein 7 (CHD7)*, which is located on chromosome 8q12. In most cases, this is a de novo, or new, mutation such that the recurrence risk of CHARGE syndrome is typically low, less than 5% if the mutation is not present in either parent (Nussbaum et al. 2007). Because the *CHD7* gene encodes a protein that is involved in altering the structure of chromosomes, it likely functions in an epigenetic manner, regulating the expression of genes that serve critical functions in early development. This accounts for the observation that not

all cases of CHARGE syndrome are due to mutations in *CHD7*, indicating that mutations in other genes can result in a similar clinical presentation. Moreover, as with other rare genetic syndromes associated with an increased risk of autism, studies of the genetic etiology of CHARGE syndrome may provide insight into the genetics of autism.

Definition

In the United States and other countries, a charter school is a publicly funded but privately run

school. These schools differ from traditional public schools because their existence is contingent upon meeting certain outcomes. When granted a charter, the school sets certain student achievement goals that must be met at the time of charter renewal. The charters are renewed every 3–5 years, depending on the district or state. School leaders at charters have increased autonomy to meet these goals. When the number of applicants for a charter school exceeds available seats, students are admitted based on a lottery.

Charter schools can be primary or secondary schools. They do not charge admission and typically are exempt from some requirements of public (state-run) schools. Students in these schools do participate in state-mandated testing. An increasing number of such schools serve children with special needs including autism.

Structure

Chromodomain-helicase-DNA-binding protein 8 (CHD8) encodes an ATP-dependent DNA

helicase located on chromosome 14q11.2 in humans. Two human isoforms of CHD8 are produced by alternative splicing, with the canonical sequence spanning 2581 amino acids and 39 exons. CHD8, originally termed Duplin upon its initial discovery, (Sakamoto et al. 2000) is a member of the chromodomain-helicase-DNA-binding protein family. The CHD family is characterized by the SNF-2-like ATPase and two chromodomains (chromatin organization modifier) (Marfella and Imbalzano 2007). Within this protein family, nine genes are organized into three subfamilies according to the presence or absence of specific functional domains. CHD8 bears most functional and structural similarity to CHD7 and CHD9, all of which exhibit a DNA-binding domain as well as a BRK domain located at the C-terminus. Conservation of CHD8 is evident across a diverse array of species including chimpanzees, rhesus monkeys, dogs, cows, mice, rats, zebrafish, and frogs, though 140 organisms have genes orthologous to the human CHD8 gene.

Function

Through its many interactions, CHD8 has been shown to serve as a global regulator of chromatin architecture and gene expression. The discovery of CHD8, initially described as an axis duplication inhibitor, was made through the observation of its novel interaction with the canonical Wnt/ β -catenin pathway (Sakamoto et al. 2000). This pathway, which is implicated in embryonic development and cellular proliferation among other biological processes, is negatively regulated by CHD8 through its binding β -catenin.

Yet the implications for CHD8 in early embryogenesis extend as well to its binding interaction with tumor suppressor protein and transcription factor p53, where CHD8 is believed to recruit histone H1, an essential component in chromatin packing and structural integrity, in order to stave off p53 transactivation activity and ultimately apoptosis (Nishiyama et al. 2009). The hypotheses as to exactly how CHD8 regulates transcription extend to evidence of its interaction with CTCF, an insulator binding protein that blocks the interaction between promoters and

enhancers. In the absence of sufficient CHD8, effects on CpG methylation and histone acetylation were observed around CTCF-binding sites, possibly interfering with proper insulation activity, chromatin structure and integrity, as well as gene regulation and epigenetic control (Ishihara et al. 2006).

Indeed, the functional diversity of CHD8 has been shown through alternate proposals that CHD8 may modulate transcription via histone H3 lysine 4 (H3K4me3) modification (Yuan et al. 2007; Rodriguez-Paredes et al. 2009; Sugathan et al. 2014; Cotney et al. 2015), associations with RNA polymerase II (Rodriguez-Paredes et al. 2009), or remodeling general chromatin architecture by other means.

Path of Physiology

CHD8 is among a small list of genes attributed the highest confidence for its documented contribution to autism spectrum disorder (ASD) risk. This level of confidence in its candidacy as an ASD risk gene is derived from the evidence of 26 de novo mutations or disruptions in the gene, identified through both targeted re-sequencing and whole exome sequencing, among individuals diagnosed with ASD, (Bernier et al. 2014; De Rubeis et al. 2014; Iossifov et al. 2012; McCarthy et al. 2014; O’Roak et al. 2012a, b, 2014; Talkowski et al. 2012) making CHD8 one of the most mutated genes in simplex ASD (Barnard et al. 2015).

Among these mutations are a number of missense variants, many of them predicted in silico to be damaging to protein function, and several implicit loss-of-function (LoF) or likely gene-disrupting (LGD) mutations that result in a premature truncation of the gene, shift in the protein reading frame, or canonical splice site variant. Recorded disruptions of the gene also include chromosomal abnormalities such as the 14q11.1 breakpoint of a de novo balanced translocation of 3q25.31 and 14q11.1 [46 XX, t_(3;14) (q25.31; q11.2)dn] (Talkowski et al. 2012).

These genetic aberrations in CHD8 further seem to exhibit some specificity at the phenotypic level, even among individuals diagnosed with

ASD. Identifying genetic specificity within ASD may ultimately accelerate the search for biologically based diagnostic tools and individualized treatment regimens for patients who exhibit syndromic subtypes of ASD. Individuals with CHD8 mutations exhibit significantly larger head circumferences, known as macrocephaly (O’Roak et al. 2012a, b; Talkowski et al. 2012; Bernier et al. 2014), gastrointestinal problems (Bernier et al. 2014), and often similarly dysmorphic facial features (Bernier et al. 2014; Talkowski et al. 2012). Indeed, one hypothesis has suggested that the observation of macrocephaly in patients with CHD8 mutations may stem from the absence of necessary binding interactions of CHD8 with transcription factors that control cell cycle regulation (Subtil-Rodriguez et al. 2014) or from interference in proper cell cycle progression due to insufficient *Chd8* protein levels (Rodriguez-Paredes et al. 2009). This support for a distinct CHD8 subtype of ASD that arises from disruptions in cellular proliferation and early developmental pathways has been recapitulated among animal models using both mice and zebrafish (Nishiyama et al. 2009; Sakamoto et al. 2000; Bernier et al. 2014).

Several studies have recently sought to explore the impact of heterozygous LoF mutations in CHD8 by investigating the downstream effects of CHD8 knockdown (Sugathan et al. 2014; Cotney et al. 2015; Wilkinson et al. 2015). While the exact mechanisms remain unclear, these studies have replicated the finding that both direct and indirect targets of CHD8 are strongly enriched for genes already known to be associated with ASD risk. Through binding interactions and indirect downregulation, CHD8 has been found to play a role in critical brain-based and neuronal development pathways that control synapse formation, neuron differentiation, and axon guidance as well as chromatin modification and transcriptional regulation.

In summary, evidence from the extensive study of CHD8 since its discovery in 2000 suggests that CHD8 may play a critical role in highly conserved evolutionary pathways. Given the evidence, it has

been proposed that CHD8 likely serves as a master regulator for gene transcription and expression and that the gene sets regulated by CHD8 may in turn tightly control the proper development of the human brain and neuronal development during a key prenatal window (Bernier et al. 2014). Mutations that drastically alter the levels of CHD8 protein likely disrupt these pathways and ultimately give rise to increased ASD risk.

PDD-NOS	Pervasive developmental disorder-not otherwise specified
ASD	Autism spectrum disorder
PPV	Positive predictive value

Description

The CHecklist for Autism in Toddlers (CHAT; Baron-Cohen et al. 1992, 1996) is a screening tool designed to capture early signs of autism in 18-month-olds by inquiring about milestones related to early social and communicative development. The CHAT consists of nine parent report items and five child observation items completed by the child’s general physician or health visitor. The parent questions (part A) assess abnormal behaviors commonly associated with autism spectrum disorders (i.e., reduced social interest, social play, pretend play, protodeclarative pointing, and joint attention), as well as developmental behaviors that are more likely to be intact in children with autism (i.e., rough and tumble play, motor development, protoimperative pointing, and functional play). The second set of questions (part B) was created to supplement the parent’s report of the child’s behavior. A trained professional administers five items measuring pretend play, protodeclarative pointing (both initiating and responding to another person’s point), eye contact, and functional play. All questions are in a yes/no format and administration time is approximately 15 min.

A high-risk score is obtained if a child fails all five items addressing protodeclarative pointing, pretend play, and gaze monitoring across parent report and clinician observation. A medium-risk score results from failing both items on protodeclarative pointing. All other children are considered to be at low risk for autism. Additionally, a two-stage screening method is recommended in which a child screens positive on the original CHAT administration, as well as upon re-administration 1 month later in attempts to reduce the likelihood of false positive cases (Baron-Cohen et al. 2000).

Historical Background

The CHAT was developed in Great Britain by Baron-Cohen and colleagues as a way for primary care physicians or home visitor nurses to screen for autism in young children. It was the first screening tool to identify autism risk in 18-month-olds. The pilot version of the questionnaire included several parent report items for each of 10 areas of development. In efforts towards quicker administration, items in the imitation domain were dropped, as these behaviors were determined to not be reliably present among most 18-month-olds (more than 20% did not), resulting in the current nine areas of development. Subsequently, only the most frequently passed question for each domain was kept and the rest of the questions were dropped, resulting in the current version of one question for each of the nine areas.

In their initial study, Baron-Cohen et al. (1992) screened 50 randomly selected toddlers from a pediatric setting (low-risk) and 41 high-risk toddlers (younger siblings of children with autism). More than 80% of the randomly selected low-risk toddlers passed all items on the CHAT. Among the high-risk group, four toddlers failed at least two of five target ASD items and later had a diagnosis of ASD at follow-up. This first study, although a small sample, suggested its utility as an ASD screening instrument within a population that had been identified as being at-risk. In a subsequent validation study screening 16,000

children using the CHAT, Baron-Cohen et al. (1996) identified three critical content areas for identifying autism, which include pretend play (parent-report and observation), eye gaze (observation), and pointing (parent-report and observation), totaling five critical items. Twelve of the 16,000 children among the general population were identified as at-risk for autism; risk status was based on a two-stage screening approach in which the high-risk score cutoff of failing all five critical items was met both at the original administration of the CHAT as well as at retest approximately 1 month later. The two-stage method was adopted to help reduce false positive cases. Ten of these children received a diagnosis of autism and two had other developmental delays, suggesting that the measure had adequate utility for use in the general population. Follow-up diagnostic evaluations at 3½ years of age indicated stability of diagnosis. In a follow-up study of the 16,000 children at age 7 years, the effectiveness of one-stage screening was compared to two-stage screening (Baird et al. 2000); see section “Psychometric Data.” In an article summarizing published research on the CHAT, Baron-Cohen et al. (2000) recommended using two-stage screening so as to ensure that failing items on the first CHAT are significant developmental concerns rather than situational concerns on the day of administration (i.e., having a “bad day”) or milder developmental delays.

Several different scoring systems and versions have been developed since the original CHAT. Scambler et al. (2001) published data on a modified scoring system for the CHAT, called the **Denver criteria**. The Denver scoring criteria differed in that they included failing a parent-report item of pretend play or pointing to show an object, as well as clinical observation of pointing impairment.

Additionally, the **Modified Checklist for Autism in Toddlers (M-CHAT)**; Robins et al. (1999) is a parent-report screening measure that was adapted from the original CHAT in order to capture the whole spectrum of disorders, rather than just Autistic Disorder. It consists of 23-item “yes or no” questions. Preliminary results in a mixed low- and high-risk sample indicated promising psychometric properties (Robins et al. 2001)

and a large low-risk sample demonstrated utility in pediatric primary care (Chlebowski et al. 2013).

The latest revision is known as the **Modified Checklist for Autism in Toddlers, Revised with Follow-Up (M-CHAT-R/F)** (Robins et al. 2009, 2014). This version formalized the two-step screening approach, using the structured Follow-Up questions for children who score at risk. The parent questionnaire is slightly shorter than the M-CHAT, consisting of 20 items. Additional changes include removing three items that exhibited poor discriminant validity, re-ordering items to reduce affirmative response bias, adding examples describing target behaviors, and simplifying wording. Children who screen positive (total score ≥ 3) complete the Follow-Up; at-risk score at Follow-Up is ≥ 2 . The M-CHAT-R/F has been adapted for electronic administration (Campbell et al. 2017; Sturmer et al. 2016) and use of drawings to illustrate items; see www.mchatscreen.com for translations including illustrations. See ► “M-CHAT” entry for more details about this instrument and its psychometric data.

Data on the **CHAT-23**, a version of the CHAT applicable for Chinese children, was published by Wong et al. (2004). This version is a combination of both the M-CHAT and CHAT in that it consists of a Chinese translation of the 23-item M-CHAT (part A) plus the five clinical observation items from the CHAT (part B). Initial data on 18- and 24-month-olds identified seven critical items from part A, and four key items in part B. The fifth item in part B assessed general developmental ability (i.e., functional play), which is thought to develop normally in autism and was not included in the statistical analysis. Screen positives on part A include failing two of seven items determined to be critical in this translation or any six of the 23 items overall; screen positives on part B include failing at least two of the four key items. Based on their results, the authors suggest a two-stage algorithm for screening. This includes universal screening using part A, followed by part B screening only for those children who screen positive on part A. See section “[Psychometric Data](#)” for a summary of psychometrics.

Another version is the **Quantitative Checklist for Autism in Toddlers (Q-CHAT)** (Allison et al. 2008), which took the form of a 25-item parent-report scale in which responders quantify behaviors based on a 5-point Likert rating scale. Likert scale response items vary depending on the question and range from, for example, “always” to “never,” “many times a day” to “never,” “very easy” to “impossible,” etc. This allows for demonstration of reduced frequency of particular behaviors that children with an ASD might exhibit, rather than requiring parents to judge absolute absence of these behaviors. In addition to the three key items identified by Baron-Cohen et al. (1996), which are pretend play, eye gaze, and protodeclarative pointing, the Q-CHAT includes other domains, such as language development and repetitive behaviors. The Q-CHAT has been used to measure clinical comparisons, not just for early ASD detection. For example, in a sample of children born premature, the Q-CHAT was used to assess social-communication outcomes in conjunction with measures of sociodemographic factors and cognitive functioning (Wong et al. 2014). Results indicated higher Q-CHAT scores (i.e., greater social-communication difficulties) relative to norms; lower cognitive functioning and ethnic minority status was associated with higher Q-CHAT scores. Additionally, the Q-CHAT has been used to measure ASD traits and sex differences at age 18–24 months and compare to testosterone levels; results have shown prenatal testosterone levels but not postnatal testosterone levels, to be related to later ASD traits and sex differences (Auyeung et al. 2012). This measure has been translated into several languages, and cross-cultural validation studies have been conducted in clinical and unselected samples in Singapore (Magiati et al. 2015), Colombia (Gutiérrez-Ruiz et al. 2019), and Italy (Ruta et al. 2019a, b).

Psychometric Data

The entire screening sample for the initial low-risk CHAT validation included 16,000 children screened at age 18 months (Baron-Cohen et al.

1996), who were later followed up when the children turned 7 years old (Baird et al. 2000) in order to calculate complete psychometric data, which requires ascertainment of missed cases or false negatives. Based on their results, there were 50 cases of autism and 44 cases of PDD-NOS in the sample. The authors compared psychometric data of the CHAT when using one-stage screening versus two-stage screening (two administrations 1 month apart). Based on one-stage screening, 10 of the 50 autism cases were identified by the high-risk score, and an additional 9 cases were identified using the medium-risk score. This yielded a sensitivity of 0.20, specificity of 0.998, and positive predictive value (PPV) of 0.26 using the high-risk score, and sensitivity of 0.38, specificity of 0.98, and PPV of 0.05 for the medium-risk score. Of all 94 ASD cases, medium-risk scoring criteria identified 33 cases whereas high-risk cutoff scores captured 11 cases. The high-risk cutoffs demonstrated a sensitivity of 0.12, specificity of 0.998, and PPV of 0.29; medium-risk scores yielded a sensitivity of 0.35, specificity of 0.98, and PPV of 0.08. When using the two-stage screening in identifying cases of autistic disorder, PPV increased to 0.75 and 0.29 for the high-risk and medium-risk cutoffs, respectively. Specificity remained high, whereas sensitivity somewhat dropped to 0.18 and 0.20 for the high-risk and medium-risk cutoffs, respectively. For all ASD cases, there was a similar pattern with PPV again increasing to 0.83 and 0.59 based on the high-risk and medium-risk scores, respectively, specificity remaining high, and sensitivity somewhat decreasing to 0.11 and 0.21 for high-risk and medium-risk cutoffs, respectively. Overall, two-stage screening increases the CHAT's PPV, which increases the likelihood that a screen positive case will receive an ASD diagnosis; however, the false positive rate is greater in the two-stage approach compared to screening at a single time point, thus reducing the measure's sensitivity (Baird et al. 2000; Baron-Cohen et al. 2000). See Table 1 for a summary of psychometric data.

The Denver criteria (Scambler et al. 2001) were based on post hoc analysis as part of their study on the CHAT as a Level 2 screener. These scoring criteria were compared to original scoring

criteria on a sample of two- to three-year-old children with ASD ($n = 26$) and other developmental disorders (DD; $n = 18$) to determine how well the CHAT distinguishes between the two groups. The Denver scoring criteria yielded 0.85 sensitivity and 1.00 specificity, whereas the sensitivity dropped to 0.65 when using the original CHAT scoring criteria, with specificity remaining at 1.00. A subset of these children (ASD $n = 19$; DD $n = 11$) participated in a follow up study two years later to assess stability of diagnosis (Scambler et al. 2006). Original CHAT scoring at Time 1 correctly classified 83% of the sample at Time 2 (five missed cases of ASD); 93% of the sample was correctly identified at Time 2 based on the Denver scoring criteria of the CHAT at Time 1 (two missed cases of ASD). The CHAT's original scoring and Denver scoring have been assessed for utility in detecting autism in Fragile X syndrome cases (Scambler et al. 2007). On a sample of 17 children (mean age = 34 months), results yielded sensitivity of 0.50 and specificity of 1.00 using CHAT scoring criteria and sensitivity of 0.75 and specificity of 0.92 using the Denver scoring criteria.

Two-stage screening with the CHAT was evaluated in a population-based cross-sectional study in Ireland (VanDenHeuvel et al. 2006). At the initial screen, 29 of 2117 toddlers demonstrated medium or high risk at 18-month developmental checkup, of which at secondary screening 7 continued to screen positive, 12 exhibited low risk, and 10 did not participate. The seven children who screened positive and five of the children who declined secondary screening completed a clinical assessment ($n = 12$), and seven children were diagnosed with ASD, yielding a prevalence of 33.1 per 10,000, 95% CI [12.3, 68.0]. Based on methodological issues, additional psychometric data could not be assessed and is not included in Table 1.

The utility of the CHAT as a tool to detect autism in children younger than 3 years was also investigated in a Swedish population (Höglund-Carlsson et al. 2010). Nurses were instructed to administer the CHAT if the child was identified to be at-risk based on developmental surveillance; those who screened positive on the CHAT were

	Part A: Fail 6/23 total items	0.84	0.85	0.79
	Part B: Fail 2/4 key items	0.74	0.91	0.85
Allison et al. 2012 (Q-CHAT-10)	ASD <i>n</i> = 126; mean age = 36 mo. Control <i>n</i> = 754; mean age = 21 mo.			
	Q-CHAT 10-item version	0.91	0.89	0.58
Raza et al. 2019 (Q-CHAT-10)	High-risk sibling <i>n</i> = 116 (with ASD <i>n</i> = 25) Low-risk control <i>n</i> = 56 (with ASD <i>n</i> = 0)			
	18-month screening	0.75	0.63	0.36
	24-month screening	0.71	0.65	0.34

Note: Details including psychometric properties from studies using the Modified Checklist for Autism in Toddlers (M-CHAT) and the M-CHAT Revised with Follow-Up (M-CHAT-R/F) are not included in this entry. See “► M-CHAT” entry

administered a subsequent CHAT. In a population of 35,990 18-month-olds, 6822 screened positive on developmental surveillance; however, only 18% of these cases were administered a CHAT (*n* = 1230), which was primarily a decision made by the nurses who reported that most often the children in those cases seemed to be non-autistic. Compared to a control study area in which

developmental surveillance as usual was being conducted, an equal number of children were referred for an ASD evaluation. The authors concluded that the use of the CHAT did not help increase the number of children who received an ASD diagnosis before age three. However, the procedures used in the study differed from those used in previous studies. Specifically, the CHAT

was not uniformly administered to the entire sample; in addition, 63% of the nurses reported having deviated from the study protocol. Therefore, one might interpret these results to indicate that when providers select a subset of cases for screening, the use of standardized screening tools may not improve detection of autism.

The psychometric properties of the CHAT-23 (Wong et al. 2004) in a sample of 212 toddlers ages 13 to 86 months yielded a sensitivity of 0.93, specificity of 0.77, and positive predictive value of 0.74 when failing two of the seven key items in part A. Failing any six from the 23 parent items resulted in a sensitivity of 0.84, specificity of 0.85, and positive predictive value of 0.79. Failing two of four key items in part B produced a sensitivity of 0.74, specificity of 0.91, and positive predictive value of 0.85. Given the sensitivity-specificity tradeoff between using the key items for screening in part A compared to part B, the authors proposed two-level screening approach in which part B is only administered to those who initially screen positive on part A. Limitations of the study included the small sample size, and that screening was administered after children had already been evaluated and diagnosed.

Initial publication of Q-CHAT (Allison et al. 2008) data compared total scores within an unselected sample ($n = 779$; mean age = 21 months) to total scores among an ASD sample ($n = 160$; mean age = 45 months). Results demonstrated a significantly higher mean score for the ASD group relative to the control group, whose range of scores approximated a normal distribution. Also, the Q-CHAT demonstrated good test-retest reliability of 0.82 and discrimination between ASD and control groups. However, similar to the CHAT-23, interpretation of findings is preliminary, given the small sample size and because screening was completed after children were already evaluated and diagnosed, which may impact how parents report about their child's behavior. The Q-CHAT has been evaluated across several ethnic groups, including in Singapore (Magiati et al. 2015), Colombia (Gutiérrez-Ruiz et al. 2019), and Italy (Ruta et al. 2019a, b). Some of these studies have compared Q-CHAT results from parents of children already diagnosed with ASD to a sample of typical children, but such use

of preselected samples has limited utility in evaluating screening tools, as this method is not consistent with how the tool was designed to be used. Additionally, parents of children with ASD may have varying degrees of ASD knowledge compared to the general population, which can affect responses.

Allison et al. (2012) sought to develop a 10-item version of the Q-CHAT on a sample of 126 preschool children with an autism spectrum diagnosis and 754 typically developing toddlers. They identified the 10 most discriminating items with a cutoff score of 3, yielding the following psychometric properties: sensitivity = 0.91, specificity = 0.89, PPV = 0.58, and internal consistency >0.85 ; however, these psychometrics should be considered preliminary until a large validation study is conducted. Raza et al. (2019) demonstrated that screening with Q-CHAT-10 distinguished high-risk siblings who were ultimately diagnosed with ASD from other high-risk and low-risk toddlers. However, specificity and PPV were below 70%, and its use as a stand-alone measure for high-risk infants was not recommended.

Clinical Uses

The CHAT is designed for use at 18-month checkups in the pediatric setting to identify children at risk for an autism spectrum disorder.

Chelation

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

Chelation involves the use of various agents to remove heavy metals from the body – typically lead – but sometimes arsenic, mercury, or other metals are the targets. Various agents can be used for this process. These agents were first developed in the treatment of poison gas inhalation during World War I and have been substantially modified and refined over the years to increase efficiency while minimizing side effects. Various routes of administration are used for these chelating agents. There are occasional uses in treatment of other diseases, e.g., those that involve excess iron storage.

As an alternative treatment, many claims have been made, but not scientifically substantiated for a range of conditions ranging from atherosclerosis to autism. The use in autism rested, in part, on the unproven suggestion that high mercury levels were involved in the production of autism. There is no scientific justification for this process in autism.

There can be significant risks to chelation – including hypocalcemia, anemia, kidney problems, and cardiac difficulties. There are reports of deaths including one child with autism. Deaths may relate to hypocalcemia. As with all non-proven treatments, particularly when some substantial risk is concerned, parents should be careful to make informed treatment choices.

Chess, Stella

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Stella Chess

- B.A., 1935, Smith College, Northampton, MA
- M.D., 1939, New York University College of Medicine, New York, NY

Major Appointments (Institution, Location, Dates)

- Psychiatry Residency, Grasslands Hospital in Eastview, NY
- 1954–1966 Assistant Professor, New York Medical College
- 1966–2007 Associate and Full Professor, New York University School of Medicine

Major Honors and Awards

- Smith College Medal, 1999

Landmark Clinical, Scientific, and Professional Contributions

Stella Chess made many important scientific contributions. She began her New York Longitudinal Study in 1956. This body of work, focused on careful observation of styles of behavior and

personality, led to the development of Chess's concept of varying temperament. Her work helped shift the field from a sole reliance on intrapsychic conflict and anxiety (as exemplified in then popular psychoanalytic work) but instead suggested the importance of understanding individual differences. Chess also elaborated the notion of "goodness of fit," e.g., relative to potential matches and mismatches in parental style and child temperament. This work led to a growing body of work on the basis of individual differences, their stability, and relationship to childhood problems. In 1971, she reported on a possible observation of an association between congenital rubella. In retrospect, the developmental course of many of the patients she first reported seemed less typical of autism, but her work focused attention on a possible biological mechanism in the condition. Chess also was noted for her pioneering work in psychiatric-pediatric liaison work and also edited an influential book series, *Annual Progress in Child Psychiatry and Child Development*, that continues to be published. She founded the first pediatric psychiatry unit at Bellevue Hospital and was a professor at NYU.

Short Biography

Born in New York to immigrant parents from Russia, Chess studied at the Ethical Culture School and then Smith College before entering NYU Medical School in 1935. She met her husband, and research collaborator, Alexander Thomas while they both were in medical school. They married in 1938. While in medical school, she worked with Laretta Bender. Chess began, in collaboration with her husband, the New York Longitudinal Study of Child Development that followed several hundred youth. During the course of their work, they identified a series of basic temperaments and parenting styles and also began to emphasize the importance of "goodness of fit" with parents. Many trainees worked with her. She continued to teach at NYU into her 90s. She was involved in training many of the leaders in the field and collaborated with Michael Rutter among others.

Child Abuse in Autism

Hillary Hurst

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Definition

Children with autism spectrum disorders are significantly more likely than typically developing children to be the victims of abuse, which encompasses emotional abuse, physical abuse, sexual abuse, and neglect.

Historical Background

Child abuse, which includes physical abuse, emotional abuse, sexual abuse, and neglect, is less

studied among children with autism spectrum disorders (ASD) than it is among typically developing children, despite their elevated risk for exposure. However, abuse among ASD and intellectual disability (ID) populations is a growing area of research and awareness, and a specific focus on sexual abuse has emerged. While previous attitudes held that individuals with disabilities were asexual and could not be negatively impacted by others' sexual behaviors, current research is more respectful of the humanity and sexuality of individuals with disabilities, including ASD. Individuals with ASD who have extremely limited or impaired functional communication skills may be particularly at risk, as perpetrators may believe that the individual with ASD will not be able to disclose their role in the abusive incidents to family members or authorities.

Current Knowledge

The Centers for Disease Control and Prevention (CDC) reported that in 2008, approximately 772,000 children in the USA were victims of maltreatment. Of these children, the majority (71%) experienced maltreatment, 16% experienced physical abuse, 9% experienced sexual abuse, and 7% experienced emotional abuse. The rates of child sexual abuse are particularly high: recent studies by the CDC suggest that 16.67% of boys and 25% of girls in the general population experience some form of sexual abuse before the age of 18. It is likely that the actual rate of sexual abuse is even higher than reported by the CDC, given the multiple reasons that victims might be reluctant to disclose or report abuse when it has happened. Also, it is important to keep in mind that the CDC reports statistics for the greater population, and does not compare rates of maltreatment based on children's disability status. However, research has consistently suggested that children with ID are at greater risk than typically developing children to be the victims of all forms of maltreatment (Sobsey 1994). Children with ID are also less likely than typically developing children to report abuse when it has

occurred. Reasons for more limited reporting include communication impairments, social knowledge deficits (e.g., not understanding that the interaction was inappropriate), and greater likelihood of attributing blame for a negative interaction to oneself due to a history of difficult social interactions. The constellation of research documenting greater exposure coupled with reduced likelihood of reporting is very concerning and highlights the importance of protecting the safety and well-being of children with ASD, ID, and other disabilities.

A great deal of what is currently understood about abuse among children with ASD comes from a landmark study by Mandell et al. (2005). This study is unique in that it looks specifically at the experiences of children with ASD, instead of ID more broadly, and considers experiences of both sexual and physical abuse. Unlike previous studies, which drew heavily from institutionalized populations, Mandell et al. recruited participants who received treatment in community settings, much like the majority of children diagnosed with ASD today. This was an important distinction because children who live in hospital and institutional settings are at a greater risk for abuse, and it is problematic to generalize findings from this population to children who live at home with their families. The results of this study revealed high rates of abuse – 18.5% of the 156 children in the sample were reported by their parents to have experienced physical abuse, and 16.6% were reported to have experienced sexual abuse – among children with ASD. While these rates are lower than the ones put forth by the CDC of all children, it is important to consider that the average age of participants in this study was 11 years and the CDC reports their statistics through age 18. Mandell et al. found that children who had experienced physical abuse were more likely than non-abused children to act out sexually, to engage in abusive behavior themselves, to attempt suicide, and to have conduct and/or academic problems. Similarly, children who had experienced sexual abuse were more likely than non-abused children to act out sexually, to engage in abusive behavior themselves, and to attempt suicide. Additionally, these children were also

more likely to engage in self-injurious behavior in addition to suicidal behavior, to run away from home, and to have had a psychiatric hospitalization. Contrary to the previous belief that children with ASD were not susceptible to the effects of abuse, the findings of this study suggest quite the opposite.

In considering recent research about child abuse and ASD, it is important to consider that the rate of abuse is likely even higher than reported since communication deficits associated with ASD may make it more challenging for victims to report abuse, and for these reports to be taken seriously, when it does occur. Some research has been conducted on victims' reactions following sexual abuse, and these findings suggest that children with ASD may respond differently from typically developing children. For example, a child with ASD who has low language abilities may engage in self-injurious or self-stimulatory behavior to try to communicate or cope with the abuse that he or she experienced. Or, a child with ASD who demonstrates echolalia may recount what a perpetrator said during an abusive episode. However, this may not be recognized for what it is by parents or caretakers, who could dismiss the behavior simply as non-functional communication or meaningless jargon. In the absence of recognizing that abuse has occurred and taking appropriate steps to intervene, the abuse could continue. Therefore, the current literature suggests that parents and caretakers of children with ASD should take note of any changes in behavior (including an increase in intensity or frequency of an existing behavior, or the appearance of a new one), as it could indicate abuse. This is not to say that changes in behavior always signal that abuse has occurred – it is prudent, however, to consider the possibility that individuals with ASD may have been exposed to abuse.

The same language impairments that may prevent children with ASD from communicating that abuse has occurred may be part of the reason why they are victimized more often than typically developing children in the first place. Perpetrators may believe that children with ASD would be less likely to report the abuse to others and, in turn, the

perpetrator would not be discovered. Also, the social deficits associated with ASD may also make children on the spectrum appealing to perpetrators. For example, the perpetrator may believe that a child with ASD can be manipulated more easily and be less likely to “fight back” against advances than a typically developing child. Unfortunately, perpetrators may take advantage of children with social difficulties by presenting themselves as a “friend.” Also, children with ASD are encouraged to cooperate with teachers, clinicians, and other professionals from a very early age, and this learned compliance may lead them to follow and not to question the motives or advances of a perpetrator.

Both large-scale and small-scale studies have suggested that children with ASD are at a greater risk for abuse and maltreatment than typically developing children. There are multiple possible explanations for this phenomenon, some of which are related to the nature of ASD symptoms. There is compelling evidence that parents raising children with ASD experience much higher levels of parenting stress and depression than parents raising typically developing children or children with other intellectual and developmental disabilities. Parenting stress and depression have each been linked as risk factors for abuse (Holden and Banez 1996; McPherson et al. 2009). Because of the unpredictability of behavior among children with ASD, parents and caregivers may at times become frustrated with their children's ASD-associated traits and instead of coping with this frustration in constructive ways, they may direct it aggressively and abusively toward their child. The frustrations that lead some parents to abuse their children with ASD may lead others to neglect them. Algood et al. (2011) examine systems-level factors to see which characteristics might contribute to the neglect of children with developmental disabilities more broadly.

When examining the rates and types of maltreatment among children with ASD, it is important to consider who the most common perpetrators are. Current research suggests that the most likely perpetrator differs depending on the type of abuse. In the general population, parents are the most common perpetrators of child

neglect. However, when it comes to the other forms of child maltreatment, perpetrators frequently fall into one of these four categories: disability service providers, acquaintances and neighbors, family members, and peers with disabilities (Sobsey 1994). This information is helpful to consider when assessing whether an individual with ASD has experienced abuse; it can also help in the development of preventative programs, which are discussed in the section below.

Future Directions

Given what is known about the heightened risk of sexual abuse among children with ASD, it is important to provide age- and developmentally appropriate sexuality training to all individuals, regardless of their disability status (Edelson 2010) and to ensure that parents understand the heightened risk and have supportive resources and respite available. While sexuality education is associated with multiple positive outcomes, it serves a particular function for individuals, such as children with ASD, who are susceptible to abuse. Sexuality education can empower individuals so that they may be proactive and take steps to prevent being victimized (although it is important to note here that sexual abuse is *never* the fault of the victim). Sexuality education is also important because it can help individuals to recognize and report sexual abuse when it has occurred. Especially for children with ASD, who may have difficulty navigating social situations and understanding the intentions of others, social skills training can serve a similarly valuable function in protecting against sexual or emotional abuse.

In light of the heightened rates of abuse among children with ASD and its associated detrimental outcomes, it is very important to have valid and reliable instruments that can determine whether a child with ASD has experienced abuse. Edelson (2010) points out that some tools that are used with typically developing children, such as interviews and anatomically detailed dolls, are inappropriate for children with ASD. Children with ASD often prefer familiar routines, environments,

and settings, and to be interviewed by a new clinician when abuse is suspected could be an upsetting and off-putting experience. Also, some of the current tools for assessing abuse require a level of verbal expression that many children with ASD do not possess. Therefore, instruments for detecting abuse must be developed specifically for the needs and capabilities of children with ASD.

Overall, more research is needed to understand the rates and types of abuse experienced specifically by children with ASD, and who is perpetrating this abuse. Additionally, more research is needed on the short- and long-term effects of abuse on children with ASD. Taken together, this information could be useful in preventative, educational programs for both children with ASD and the adults in their lives. Also, this information could help in the interventions and treatments for children who have been victimized.

Definition

Children with autism spectrum disorder (ASD) present with a wide range of complex needs related to their mental and physical health. To

adequately address the various needs present in ASD, more families are being referred to ASD specialty clinics. Families who receive services at ASD specialty clinics often come for multiple visits with many interdisciplinary providers (e.g., physicians, psychologists, speech and language pathologists, etc.). For example, there is often an initial diagnostic appointment with a medical and/or psychological provider. After diagnosis, families are frequently referred for further comprehensive assessments related to their cognitive (with neuropsychologists), language (with speech and language pathologists), and physical (with occupational and/or physical therapists) needs.

The provision of specialty services is often from interdisciplinary providers across multiple visits to the clinic, including an initial appointment, the diagnostic evaluation, and follow-up care. Given that families of children with ASD are frequent consumers of specialty services, it is important to examine appointment attendance and alignment with providers about ASD diagnosis. When children are not receiving intervention, families are less likely to keep their initial appointment. It is possible that children who are not receiving intervention are presenting with minimal or inconsistent symptoms that could be temporarily extinguished. As a result, their parents may change their minds when it comes to keeping their initial appointment. These families may be reticent to follow through with their initial appointment seeking due to lack of familiarity with the diagnostic and treatment process. It is essential to spend more time scheduling and providing these families with essential resources to make them more comfortable about seeking services. More specifically, families may benefit from live conversations with a clinic triage specialist. This specialist could inquire about the nature of their concern, and explain the evaluation process, and, where appropriate, assist with the identification of local resources.

Families residing long distances and having older children are less likely to keep their initial and follow-up appointments. Families that live far distances have more difficulty accessing and utilizing specialty care services and, therefore, may rely more heavily on the school system for

services. Older children may be presenting with less severe symptoms. Therefore, these parents may not be scheduling their initial appointment because older and/or less symptomatic children are not experiencing clinically significant impairments that are interfering with daily life and others have tolerated their differences more easily. For these families, more refined communication is necessary to explain the importance of initial visits and follow-up care in order to support parents in service utilization. It is important that parents perceive keeping their appointment to have a high benefit to cost ratio.

African-American families are less likely to keep their initial appointment and express initial doubts with providers about the diagnosis. Therefore, there are barriers that are preventing African-American families from utilizing specialty care services despite them taking initiative. It is important for service provision systems to identify and address the barriers that African-American families may experience during the critical period from service initiation to utilization. African-American families' pre-visit diagnostic beliefs are more likely to be misaligned with providers' delivery of an ASD diagnosis. There is a stigma associated with being "labeled" with a mental health diagnosis, and this is particularly true for ethnic and racial minority families. Lack of alignment may be one probable mechanism through which disparities arise (i.e., later diagnosis, more visits before diagnosis, and/or different diagnosis) between children who are African-American and other races compared to White children. In order for families and providers to be aligned in their diagnostic beliefs, it is imperative that providers communicate in culturally competent ways about ASD symptomology, as well as early detection and intervention.

Description

Introduction

Youth diagnosed with autism spectrum disorder (ASD) appear to be at significantly higher risk for a co-occurring emotional and/or behavioral disorder relative to the general pediatric population. According to the *Diagnostic and Statistical Manual of Mental Disorders-Fifth Edition* (DSM-5; American Psychiatric Association [APA] 2013) – approximately 70% of individuals with ASD are likely to have one and 40%

two or more co-occurring disorders. When rendering a diagnosis, the DSM-5 now requires evaluators to specify whether ASD is accompanied by a co-occurring mental or behavioral disorder, which oftentimes requires specific treatment. Therefore, there is a need for reliable and valid measures of emotional and behavioral disorders for youth with ASD.

The Achenbach System of Empirically Based Assessment (ASEBA) consists of several norm-referenced paper and pencil rating scales that were developed to assess for adaptive competencies and a broad range of emotional and behavioral disorders in children and adolescents. Two forms are available for parents: the Child Behavior Checklist 1.5–5 (CBCL 1.5–5; Achenbach and Rescorla 2000) which is used for children aged 1.5–5 years and the Child Behavior Checklist 6–18 (CBCL 6–18; Achenbach and Rescorla 2001) which is used for youth aged 6–18 years. Three other forms are also available: the Caregiver/Teacher Report Form for 1.5–5-year-olds, the Teacher Report Form (TRF) for 6–18-year-olds, and a Youth Self-Report (YSR) for 11–18-year-olds. The various forms that comprise the ASEBA system allow for data integration across multiple informants which provides an understanding of whether and how emotional and/or behavioral disorders manifest across settings. These scales have been normed in many societies around the world, and they reflect one of the best studied measures developed for youth (see Berube and Achenbach 2015). These rating scales assess for emotional and behavioral disorders that are most often observed in youth with ASD such as anxiety, depression, withdrawal, social problems, attention problems, and aggression.

This review focuses on the emotional and behavioral disorder scales of the CBCL 1.5–5 and CBCL 6–18. These ASEBA scales have received the most attention in studies of youth with ASD. Empirical data suggest that these two measures have utility for the assessment of co-occurring disorders in this population.

CBCL Scales

The CBCL 1.5–5 and the CBCL 6–18 contain items pertaining to specific emotional and behavioral responses. Parents rate each item according to how true each statement is about their child: 0 “Not true,” 1 “Somewhat or sometimes true,” or 2 “Very true or often true.” Additionally, several open-ended items allow respondents to provide additional information that may be important for an evaluator to know about the child. The CBCL 1.5–5 ratings describe a child’s functioning during the last 2 months, and ratings on the CBCL 6–18 describe functioning during the past 6 months. Administration time is generally 10–20 min. Each measure can be scored by hand or by ASEBA software.

The CBCL 1.5–5 and CBCL 6–18 each contain two sets of scales: the empirically derived and DSM-oriented scales. The *empirically derived* scales were developed through factor analysis of data collected from a United States standardization sample. Both the CBCL 1.5–5 and the CBCL 6–18 contain two kinds of empirically derived scales. The “narrowband,” or syndrome scales, assess a wide range of specific emotional and behavioral syndromes (e.g., attention problems, social problems, aggressive behavior). The “broadband” scales are called the *Internalizing Domain* and *Externalizing Domain* which assess for broader classes of emotional (internalizing) and behavioral (externalizing) disorders. The *DSM-oriented* scales were *conceptually derived* and were meant to correspond to broad diagnostic categories in the *Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition* (DSM-IV; APA 1994). These scales were recently updated to be more consistent with the DSM-5 (APA 2013), and this is discussed below. The empirically derived and DSM-oriented scales are both norm referenced. Scale scores can be plotted on profiles that allow clinicians to readily examine relative scale elevations across several problem areas.

The CBCL 1.5–5 and CBCL 6–18 are scored and interpreted similarly. The raw scores for items within each of the empirically derived and DSM-oriented scales are summed and converted to

norm-referenced T-scores ($M = 50$, $SD = 10$). A Total Problems T-score is also available and is determined by the sum of all item scores. One set of norms is provided for the CBCL 1.5–5, and separate norms are provided for each gender within the 6–11 and 12–18 year age ranges on the CBCL 6–18. “Clinically significant” elevations are indicated by T-scores ≥ 64 on the broadband scales and ≥ 70 on the syndrome scales. “Borderline” elevations range from 60 to 63 and 65 to 69 on the broadband and narrowband syndrome scales, respectively. These qualitative categories reflect symptom severity, and scores falling within either category suggest the need for a diagnostic assessment.

Historical Background

Studies of the CBCL in ASD Samples

Most studies of the CBCL in samples of youth with ASD examined the extent to which the syndrome and broadband scales discriminated between those with and without ASD. Significant methodological differences were observed across these studies that included varied approaches to confirming an ASD diagnosis, whether the youth were evaluated for a co-occurring disorder, the clinical status and characteristics of non-ASD comparison groups (e.g., typically developing, those with non-ASD developmental disorders or psychiatric disorders), and the specific ASEBA measure used (e.g., see Biederman et al. 2010; Bolte et al. 1999; Duarte et al. 2003; Hurtig et al. 2009; Kanne et al. 2009; Ooi et al. 2010). One consistent finding that emerged from these studies was that youth with ASD often scored significantly higher than youth without ASD across several scales. Many times youth with ASD scored significantly higher than comparison groups on the *Withdrawn/Depressed*, *Social Problems*, and *Thought Problems* scales. However, it is not clear whether scale elevations were related to the presence of co-occurring emotional and behavioral disorders rather than the ASD. Base rate information on specific CBCL profiles would be helpful to

understand how unique such profiles are to the ASD population because recent studies indicated that the CBCL scales are not measures of ASD-related behavior (see Magyar and Pandolfi 2017; Pandolfi et al. 2014).

Although more empirical data are needed, several recent studies provided psychometric support for the CBCL 1.5 and CBCL 6–18 as reliable and valid measures of emotional and behavioral disorders in youth with ASD (see Magyar and Pandolfi 2017; Pandolfi et al. 2012, 2014). The results supported the unidimensionality of nearly all CBCL 1.5–5 and CBCL 6–18 empirically derived syndrome scales, which indicated that each scale measured one construct. The lone exception was the CBCL 1.5–5 *Sleep Problems* scale which was found to consist of two factors: *dysssomnias* and *parasomnias*. The two factor internalizing-externalizing factor structure was supported for both of these measures, consistent with Achenbach and Rescorla (2000, 2001). Scale reliability was generally good to excellent across the syndrome and broadband scales of each measure, although the reliabilities of the *Somatic Complaints* (CBCL 1.5–5) and *Thought Problems* scales (CBCL 6–18) were somewhat lower than desired for a screening measure.

To date, only one study provided evidence on the diagnostic accuracy of the CBCL 6–18 empirically derived scales for identifying co-occurring emotional and behavioral disorders in youth with ASD (Pandolfi et al. 2012). All youth were evaluated for ASD using the Autism Diagnostic Interview- Revised (ADI-R; Rutter et al. 2003) and the Autism Diagnostic Observation Schedule (Lord et al. 2002). Co-occurring psychiatric disorders were evaluated through a standardized multi-method assessment protocol which included the Schedule for Affective Disorders and Schizophrenia – Childhood Version (K-SADS; Kaufman et al. 1996), a semi-structured diagnostic interview. In addition to between-group differences across several empirically derived scales (i.e., ASD only vs. ASD + co-occurring emotional and/or behavioral disorders), the CBCL 6–18 demonstrated good sensitivity

(>.80) for identifying co-occurring depression, anxiety, attention-deficit/hyperactivity disorder (ADHD), and oppositional defiant disorder (ODD) in individuals with ASD. The specific scales with favorable sensitivity were those that were conceptually consistent with the target disorder under investigation. However, specificity was generally low. A subsequent study on the CBCL 6–18 found that those scales that were purported to assess for emotional problems were not measures of ASD: the vast majority of the individual differences in scores for youth on these scales were related to co-occurring emotional disorders, and not to their ASD symptoms (see Pandolfi et al. 2014).

We are aware of only one study on the CBCL 6–18 DSM-oriented scales in youth with ASD (see Magyar and Pandolfi 2017). The only scales evaluated were the *Affective Problems* (recently renamed *Depressive Problems*) and *Anxiety Problems* scales. Findings indicated that each of these scales reliably measured a single construct. The scales did not correlate with the ADI-R current behavior algorithm, but they did correlate with the K-SADS. The results indicated that the scales measured what they purported to measure: *Affective Problems* measured depression and *Anxiety Problems* measured anxiety. Neither scale appeared to be a measure of ASD-specific problems. With respect to diagnostic accuracy, sensitivity was acceptable for both scales, and specificity was acceptable for *Affective Problems* but somewhat low for *Anxiety Problems*.

Research findings lend support for using the CBCL to assess youth with ASD in clinical and research settings. Replication of findings is needed, especially within important subgroups within the ASD population: such as within specific age groups, each gender, and those with various levels of autism severity, language impairment, and cognitive ability. This would provide much more specific information to assist in the clinical decision-making of those professionals who work with this heterogeneous population, many of whom are often in need of both ASD treatment and specific treatment for co-occurring disorders.

Psychometric Data

Test Development and Psychometric Properties

Achenbach and Rescorla (2000, 2001) reported several lines of evidence that supported CBCL scores as indicators of emotional and behavioral disorders in the general population. Although there is close correspondence in the kinds of syndromes that are measured by the CBCL 1.5–5 and CBCL 6–18, some differences exist and are detailed next.

Factor analyses of test items were used to help construct the empirically derived scales for both measures. For the CBCL 1.5–5, seven first-order factors were identified, and these represented the seven narrowband syndrome scales. Two higher order factors were also identified which reflected the broadband scales. One was called the *Internalizing Domain* which consisted of four emotional syndromes (i.e., the first-order factors) that were labeled *Emotionally Reactive*, *Anxious/Depressed*, *Somatic Complaints*, and *Withdrawn*. The other higher order factor, named the *Externalizing Domain*, consisted of two behavioral syndromes which were called *Attention Problems* and *Aggressive Behavior*. One first-order factor, *Sleep Problems*, did not belong to either higher order factor.

A slightly different set of syndrome scales was found for the CBCL 6–18. While it too contained two higher order *Internalizing* and *Externalizing Domains*, the syndromes that belonged to each were different. The *Internalizing Domain* contained the *Anxious/Depressed*, *Withdrawn/Depressed*, and *Somatic Complaints* syndrome scales. The *Externalizing Domain* contained the *Rule-Breaking Behavior* and *Aggressive Behavior* syndrome scales. Three other syndrome scales did not belong to either broadband scale: *Social Problems*, *Thought Problems*, and *Attention Problems*. These are considered mixed syndrome scales because they had sizable factor loadings on both broad domains in the Achenbach and Rescorla (2001) factor analyses.

The DSM-oriented scales were initially developed to be conceptually consistent with broad DSM diagnostic categories. The CBCL 1.5–5

scales included *Affective Problems* (now called *Depressive Problems*, see below), *Anxiety Problems*, *Pervasive Developmental Problems* (now called *Autism Spectrum Problems*, see below), *Attention Deficit/Hyperactivity Problems*, and *Oppositional Defiant Problems*. The CBCL 6–18 scales included *Affective Problems* (now called *Depressive Problems*), *Anxiety Problems*, *Somatic Problems*, *Attention Deficit/Hyperactivity Problems*, *Oppositional Defiant Problems*, and *Conduct Problems*. The DSM-oriented scales complement the empirically derived scales to assist practitioners in the differential diagnostic process. Achenbach and Rescorla (2000, 2001) and Achenbach (2014) described scale construction in detail which included experts in child psychology and psychiatry to help devise scale content. The DSM-oriented scales that were conceptually aligned with the DSM-IV received much psychometric support (described below), and these scales were recently revised to be consistent with the DSM-5.

The revisions featured name changes to some of the scales, and only minor content changes to two of the scales (see Achenbach 2014). On the CBCL 1.5–5, the former *Pervasive Developmental Problems* was renamed *Autism Spectrum Problems*, and the scale's updated content changed only with the deletion of one item. *Affective Problems* was renamed *Depressive Problems* on both the CBCL 1.5–5 and CBCL 6–18. On the CBCL 6–18, the *Anxiety Problems* scale now features three new additional items.

Both test manuals provide several lines of psychometric evidence for the empirically derived and DSM-oriented scales. It is noted that the psychometric evidence pertaining to the DSM-oriented scales was gathered prior to the recent revision to these scales. The authors substantiated the CBCL's content validity by citing years of research, clinical experience, and consultation with several stakeholders in children's mental health assisting in the item selection process. Interested readers should consult the technical manuals for more information about the content of specific scales.

The data presented in each technical manual indicate that the CBCL 1.5–5 and CBCL 6–18

appear to be sufficiently reliable for clinical use with the general population. The technical manuals each reported internal consistencies $\geq .89$ for the *Internalizing* and *Externalizing Domains* and for *Total Problems*. For the CBCL 1.5–5, some of the narrowband and DSM-oriented scales had internal consistencies $< .70$, so it is especially important to interpret these scales in conjunction with other clinical data (see Achenbach and Rescorla 2000). Reported odds ratios for the CBCL 1.5–5 and CBCL 6–18 indicated that those with scale scores in the borderline/clinically significant ranges were far more likely to be referred for mental health services than youth with scores below these ranges. A related finding indicated that a sizable percentage of the youth who were referred for mental health services had scores in these elevated ranges. Achenbach and Rescorla (2000, 2001) also presented significant correlations between CBCL scores and DSM diagnoses. These data suggested that youth with elevated scores on any of the empirically derived or DSM-oriented scales should be referred for a diagnostic assessment.

Clinical Uses

The CBCL 1.5–5 and CBCL 6–18 appear to have utility in ASD assessment. These measures assess for the kinds of disorders that occur at fairly high rates in youth with ASD. These include depression, anxiety, ADHD, and ODD. The empirically derived syndrome scales assess for disorders that cut across DSM categories. These scales can inform practitioners about the range of possible emotional and/or behavioral disorders that might affect an individual. Because the DSM-oriented scales are conceptually consistent with broad DSM-5 diagnostic categories, they can be used to assist in: (a) further understanding the nature of elevations on the syndrome scales, (b) screening for specific emotional and/or behavioral disorders, or (c) diagnostic decision-making.

The CBCL 1.5–5 and CBCL 6–18 should be considered for routine use in ASD *diagnostic assessment*. This is particularly important given that the DSM-5 requires specifying whether a

youth diagnosed with ASD exhibits co-occurring mental and/or behavioral disorders. For those children who do not initially present with a co-occurring disorder, regular *screening* throughout childhood should be completed as a means of monitoring for the emergence of one or more emotional or behavioral disorders. This is particularly so for critical developmental periods such as the later part of early childhood where difficulties with attention and impulsivity may interfere with full participation in an inclusive school setting and in adolescence where increasing self-awareness might increase risk for depression and anxiety. Early detection is critical to informing *treatment planning* specific to the disorder of interest. Without appropriate treatment, the co-occurring disorder might result in additional personal distress and functional impairment for the affected child which might moderate response to ASD-specific treatment. This could result in more restrictive interventions and/or placement, neither of which necessarily addresses the underlying emotional or behavioral disorder. Including the CBCL in ASD intervention *progress monitoring* can help evaluate the child's *response to any interventions* that may be implemented. Finally, the CBCL may play an important role in *eligibility determination* for educational and social services.

Child Language

► Normal Language Development

Child Psychotherapy

Christie Enjey Lin

Departments of Education and Psychiatry, Child and Adolescent Psychiatry, University of California, Los Angeles, CA, USA

Synonyms

Clinical psychology; Mental health interventions

Definition

A therapeutic interaction between a child (the client) and a trained therapist to alleviate the child's distress and improve functioning in everyday life. Child psychotherapy is provided by licensed clinicians (e.g., clinical psychologists, clinical social workers, child and family counselors) using a range of therapeutic approaches and strategies in order to alter feelings, thoughts, attitudes, or behaviors. The broad goals of therapy are to improve adjustment and functioning in both intrapersonal and interpersonal spheres and to reduce maladaptive behaviors. Often more specific goals are set for individual clients, depending on the therapeutic modality employed (e.g., Behavior Therapy). Child psychotherapy can include the child's parents as well as other significant members of the child's family and community.

which, “Children’s preferences guide the selection of materials; adults provide support and encourage, but do not require, that materials are used and activities are carried out in the desired way. Rather than adult-supplied consequences for certain behaviors, internal, naturally occurring reinforcers are assumed to provide the motivation for learning” (National Research Council [NRC] 2001, p. 136). However, other authors note that some children may not learn skills following a “typical” developmental progression and may not provide sufficiently diverse interests to allow educators to follow a child’s interests and therefore may be challenged to teach across variety of priority areas (Volkmar and Wiesner 2009). Volkmar and Wiesner (2009) also note that there is relatively less research on developmental, child-centered approaches than behavioral approaches, and effective implementation of child-centered approaches likely require highly skilled interventionists. The National Research Council (2001) suggested that for children with fewer appropriate initiations, a behavioral approach may be more appropriate than a child-centered approach and noted that more research is needed to demonstrate the effectiveness of child-centered approaches and relative effectiveness compared to other approaches. In contrast, a child-centered approach may be appropriate for children with a variety of interests, thus facilitating teaching across a variety of skills.

Childhood Aphasia

Courtenay Norbury

Psychology Department, Royal Holloway,
University of London, Egham, Surrey, UK

Synonyms

Congenital aphasia; Developmental dysphasia;
Language disorder; Specific language impairment

Definition

Aphasia is derived from the Greek word *aphatos*, meaning “speechless,” and is characteristically used to describe the profile of language impairments seen in adults after a stroke or other focal neurological lesion. In the early nineteenth century, physicians and neurologists such as Gall (1935, cited in De Montfort Supple 2010) described seemingly similar language impairments in children. These children could not speak but had apparently normal understanding of language and did not appear to have general cognitive impairments. The term *congenital aphasia* was first used by Vaisse in 1866 (cited in De Montfort Supple 2010), and related terms such as *developmental aphasia* or *dysphasia* were widely used until the mid-twentieth century. The assumption behind the use of these terms was that the neurobiological source of language impairment in children was similar to adult case; however, in recent years, it has become clear that most developmental language disorders do not arise from focal neurological insults. Instead, anomalies in brain development are subtle and not deterministic of language ability. There is also considerable evidence that the etiology of developmental language disorders is more typically genetic, rather than the result of acquired brain damage (Bishop 2009). Finally, most investigators would agree that the boundary between language impairment and normality is somewhat arbitrary, rendering the use of a “medical” term or “disease” category inappropriate (Norbury et al. 2008).

The notion that language could be impaired in the context of “spared” capacities in other aspects of development led to labels such as *specific language impairment (SLI)* replacing *dysphasia*. However, in practice, it is rare to see such discrete linguistic impairments in a developing child, and there is continuing controversy about how best to describe children with more specific language difficulties (Bishop 2010). In addition, there is considerable debate about the nature of language impairment in autism spectrum disorders and whether some children with ASD also have a comorbid SLI (Tomblin 2011). In practice, it is preferable to describe the nature of the child’s language difficulties in detail without recourse to diagnostic labels that make assumptions about etiology.

CARS; CARS, Second Edition, High-Functioning Version; CARS, Second Edition, Questionnaire for Parents or Caregivers; CARS, Second Edition, Standard Version; CARS2-HF; CARS2-QPC; CARS2-ST

Description

The CARS has a long-standing history as one of the most widely used diagnostic instruments for ASD. A trained observer rates an individual's behavior on 14 items and provides a general impressions score, each of which is rated on a 7-point Likert scale (1–4 with ½ points). Scores represent severity of deviation compared to expectations for one's peers of the same chronological age: a score of 1 represents functioning within normal limits, whereas a score of 4 represents severely abnormal functioning. The CARS total score ranges from 15 to 60 with higher scores indicating a higher probability or severity of autism. The CARS was intended to be used regardless of age or level of functioning. In

2010, the CARS was refined, and separate forms were created based on a person's developmental level. The CARS2-HF was developed for use with individuals over age 6 years, with IQs above 80, and intact verbal communication skills. The CARS2-ST (which is identical to the original CARS) continues to be used for all children under age 6 years and for individuals over age 6 years either with IQ scores of 79 or lower, or who have impaired communication skills (Schopler et al. 2010).

The 14 behavior domains from the CARS and maintained on the CARS2-ST include (1) relating to people; (2) imitation; (3) emotional response; (4) body use; (5) object use; (6) adaptation to change; (7) visual response; (8) listening response; (9) taste, smell, and touch response and use; (10) fear or nervousness; (11) verbal communication; (12) nonverbal communication; (13) activity level; (14) level and consistency of intellectual response; in addition to (15) general impressions. The CARS2-HF maintains the general structure of the CARS, but it does not include imitation and activity level. Instead, it adds social-emotional understanding and thinking/cognitive integration skills. Behavioral descriptions of several other items were also modified to be more applicable for individuals with a higher IQ (Schopler et al. 2010). When rating each domain, a rater considers the peculiarity, frequency, intensity, and duration of a behavioral concern. Brief descriptions of the behaviors to be observed are provided as anchors on the rating forms, but a more detailed description, including a definition and particular considerations for each item, is provided in the CARS2 manual.

The CARS2-QPC is a new form in the second edition. It is an unscored questionnaire completed by others who know the person being evaluated well. The CARS2-QPC can also provide information about a person's early development, which is not captured by the behavioral observations on the CARS2-ST and CARS2-HF, and provide examples of behavior concerns that the parent or caregiver notices. Schopler et al. (2010) stated that parents or other caregivers are not to complete either the CARS2-ST or CARS2-HF but should provide information on the CARS2-QPC, which

can then be used as a guide during a diagnostic or other direct interview.

The CARS surveys a wide range of behaviors. These behaviors related to different conceptualizations of ASD at the time the CARS was developed, but not all of them relate to the DSM-IV-TR or to an earlier predecessor, the DSM-III-R. Although an interested user could compare an individual's score on specific items to any of the diagnostic criteria on which the CARS is based, including the DSM-IV, a weighted score based on the current conceptualization of ASD is not available.

Historical Background

The CARS was developed by Dr. Eric Schopler and colleagues in North Carolina to complement their outpatient treatment program, Division TEACCH. It was included as part of their diagnostic process and educational planning, often being completed as part of the Psycho-educational Profile. Prior to its inception in DSM-III (American Psychiatric Association 1980), there were multiple definitions and diagnostic criteria for what is called ASD today. Schopler and colleagues developed the CARS as their own rating system to distinguish between ASD and other developmental disorders (Reichler and Schopler 1971; Schopler et al. 1980) in an effort to overcome limitations of existing classification systems and diagnostic measures. The CARS was originally called the Childhood Psychosis Rating Scale because it had a broader conceptualization than Kanner's original definition of autism. The name was changed to the CARS as the definition of autism expanded beyond Kanner's strict definition.

The behavior domains of the CARS are largely based on the British Working Party's diagnostic criteria for childhood psychosis (Reichler and Schopler 1971), but it also includes items based on Kanner's primary features of autism and the criteria proposed by Rutter and by Ritvo and Freeman (Schopler et al. 1980, 1988). Although most items were chosen because of their relation to the diagnostic criteria at the time, others were

included because of their clinical or educational relevance (e.g., object use, visual response, auditory response, and taste, smell, and touch response and use). From the time it was developed, the CARS was integrated with the TEACCH program to integrate assessment and intervention.

Psychometric Data

The CARS classifies a person as having minimal-to-no symptoms of ASD, mild-to-moderate symptoms, or severe symptoms of an ASD. Classification cutoffs were originally determined by examining the distribution of CARS scores in a sample of 537 children. Initially, a cutoff of 30 distinguished optimally between those with and without ASD (Schopler et al. 1980). However, the recommended cutoff scores have changed with time and now vary by age and CARS2 form.

In the development sample, the cutoff of 30 on the CARS had a sensitivity of .88 and specificity of .86 (Schopler et al. 1988). Other studies have found similar results with children. Some researchers, however, have recommended higher cutoffs for very young children and lower cutoffs for adolescents and adults. In one large study, a cutoff of 30 was supported among 4-year-olds, but a cutoff of 32 was optimal among 2-year-olds, since this resulted in better specificity (Chlebowski et al. 2010).

On the CARS2-ST, the cutoff of 30 was maintained for all children under age 13 years, but a cutoff of 28 best distinguished between minimal-to-no symptoms of ASD and mild-to-moderate symptoms of an ASD for children over age 13 years. The CARS2-HF also uses a cutoff of 28 to distinguish between minimal-to-no symptoms of ASD and mild-to-moderate symptoms of an ASD. In the CARS2-HF development sample, this resulted in a sensitivity of .81 and a specificity of .87 (Schopler et al. 2010).

The CARS is strongly related to level of functioning. It may falsely identify individuals with language impairments and cognitive impairments as having an ASD. This may be acceptable clinically for diagnostic screening but not for research requiring precise diagnostic distinctions. The

magnitude of the correlations between intellectual and adaptive functioning and CARS scores is quite high (approximately $r = .7$). Although the CARS2-HF was developed to address this weakness, its relationship with IQ has not been researched at the time of this writing.

The CARS has demonstrated good concordant validity with clinical judgment and with other ASD diagnostic instruments, including the Autism Diagnostic Interview-Revised, and the Autism Diagnostic Observation Schedule. It has also shown good convergence with ASD rating scales, including the Autism Behavior Checklist, Real-Life Rating Scale, and the Social Responsiveness Scale.

Evidence for the reliability and validity of the CARS was originally presented by Schopler et al. (1980) for 537 children assessed over a 10-year span as part of the TEACCH program. Internal consistency was .94. Other investigators have replicated this high level of internal consistency for the CARS and the CARS2-ST. Among the 994 participants in the CARS2-HF development sample, coefficient alpha was .96. However, several investigations of the CARS have found negative corrected item-total correlations, specifically for the consistency of intellectual response item.

Early investigations of inter-rater reliability focused on ratings made by other professionals without specialized training in ASD (Schopler et al. 1988). These and subsequent evaluations of inter-rater reliability have found high agreement on diagnostic classifications but lower agreement on specific items. Schopler et al. (2010) found similar results with the CARS2-HF development sample.

Test-retest reliability for the CARS has been examined with a range from as little as 3 months to more than 3 years between assessments. Across these studies, CARS scores are relatively stable ($r_s > .70$), though there is some evidence that scores decrease over time (e.g., Mesibov et al. 1989). Test-retest reliability has not been evaluated for the CARS2-HF at this time.

The CARS has been translated into several languages, including French, Japanese, Swedish, Icelandic, Indian, Spanish, and Korean. Diagnostic cutoffs vary for the different versions, but

overall, they have shown similar psychometric properties as the CARS. Evidence published in English for internal consistency, inter-rater reliability, and diagnostic sensitivity and specificity is available for the Japanese, Swedish, Icelandic, and Indian versions (Nordin et al. 1998; Russell et al. 2010; Saemundsen et al. 2003; Tachimori et al. 2003).

Clinical Uses

The CARS and the CARS2 were designed to be part of a comprehensive diagnostic evaluation for an ASD. Professionals other than clinicians have been shown to make reliable and valid ratings on the CARS after a modest level of training. The CARS also requires a rater to have some knowledge of age-appropriate functioning within each of the behavioral domains. With such training, the tool has been used successfully in clinical and educational settings, as part of a caregiver interview, in a chart review, and as a rating scale. Although it is possible to complete the CARS2-ST based on information from a single source, the CARS2-HF requires that multiple sources of information be considered, one of which must be a direct observation of the person being rated. Multiple sources of information and a behavioral observation are not required for the CARS2-ST but would benefit the diagnostic process. It is recommended that direct behavioral observation by the trained observer be given greater weight in scoring than other information if they conflict (Schopler et al. 2010).

Despite being designed to be completed by a trained clinician, the CARS has been used, with or without adaptations, as a parent rating scale. The CARS2 manual recommends that parents do not complete the CARS2-ST or CARS2-HF as a rating scale. Rather, the unscored CARS2-QPC should be completed, which can guide an interview and provide additional developmental information not captured on the CARS as part of the overall diagnostic process. The psychometric properties of the CARS, when used as a parent rating scale, have not been adequately studied.

The CARS has also found uses within research studies (see Schopler et al. 2010 for examples). It has provided an ASD severity rating or supported an ASD diagnosis. The CARS has also been used as an outcome measure for intervention studies, medication trials, and developmental studies. As an outcome measure, the CARS has shown to be sensitive to treatment effects and to maturational changes.

Childhood Psychosis

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

Childhood schizophrenia

Definition

In common use, the term psychosis implies a loss of contact with reality. Typical psychotic phenomena include hallucinations (perceiving things that others do not), delusions, and other behaviors (e.g., catatonia). Often individuals with psychosis have trouble structuring their thinking (a thought disorder). In adolescents and adults, psychosis and psychotic phenomena can arise because of psychiatric or medical illness or exposure to certain substances (e.g., hallucinogenic drugs). In common use, the term is rather broad including a range of conditions. Psychiatric disorders associated with psychosis include schizophrenia and bipolar type 1 disorder (what previously was

termed manic-depressive illness). Psychotic phenomena can be seen in various other conditions and may be more likely with stress.

In children, awareness of psychosis and psychotic phenomena is a relatively historically recent phenomenon (e.g., until the work of Maudsley in the 1800s, it was assumed children were protected from such phenomena). However, the description of what we now recognize as schizophrenia (or as it was once termed *dementia praecox*) led to rapid extension to children (*dementia praecoxissima* (de Sanctis 1906)). Kanner's use of the term autism (Kanner 1943) quickly led to confusion over the issue of whether we now think of as autism is a form of schizophrenia (see Volkmar and Tsatsanis 2002) since the term autism had earlier been used to describe self-centered thinking in schizophrenia (see Volkmar 1996 for a discussion). It took several decades before it became clear that this was not in fact the case and that autistic disorder was a distinctive condition (Kolvin 1971; Rutter 1972).

Given the major changes in children's understanding of reality, the term psychosis can be problematic in childhood. Before puberty, the prototypic psychotic disorder, schizophrenia, is profoundly uncommon although psychotic phenomena can be observed, e.g., in relation to stress, or as isolated phenomena. After age 5, the presence of psychotic symptoms is more concerning, and various factors (medical conditions, drug abuse) can produce such symptoms.

Childhood Schizophrenia

Nitin Gogtay

Division of Child and Adolescent Psychiatry,
National Institutes of Mental Health, Bethesda,
MD, USA

Synonyms

[Pediatric onset schizophrenia](#); [Very early-onset schizophrenia](#)

Short Description or Definition

Childhood-onset schizophrenia is defined by onset of psychosis before age 13 and is diagnosed using unmodified DSM-IV criteria for diagnosis of adult-onset schizophrenia.

Categorization

Although the existence of childhood schizophrenia was recognized since early in the twentieth century (Kraepelin 1919; Nicolson and Rapoport 1999), the nosological status of schizophrenia in children was controversial for many years, and the Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II) category “childhood schizophrenia” included other psychotic disorders in children, as well as autistic disorder, thus limiting the usefulness of early studies. The landmark studies by Kolvin (Kolvin 1971; Kolvin

et al. 1971a, b, c, d, e), however, clearly differentiated schizophrenia with onset in childhood from pervasive developmental disorders, and subsequent research over the years has established the clinical and neurobiological continuity between the childhood- and adult-onset schizophrenia. Thus, COS is more appropriately categorized as the childhood counterpart of the typical adult-onset illness (Gogtay 2008).

Epidemiology

COS is rare and difficult to diagnose. As a result, it is hard to estimate the exact incidence. Furthermore, even today, high rates of misdiagnosis remain as transient psychotic symptoms can occur in healthy children (Caplan 1994; McGee et al. 2000; Schreier 1999), and fleeting hallucinations are not uncommon in nonpsychotic pediatric patients (Lukianowicz 1969; McKenna et al. 1994b) particularly in response to anxiety and stress (Rothstein 1981). Fully developed psychotic disorders in children, however, are rare and tend to be more severe than their adult counterparts (Childs and Scriver 1986), and recent data suggest that psychotic symptoms probably exist as a continuous phenotype rather than an all-or-none phenomenon (Poulton et al. 2000).

Based on the NIMH COS study experience (described later), where over the past 20 years, we have evaluated over 3,000 referrals with a potential diagnosis of schizophrenia. However, diagnosis could be confirmed only in 122 cases to date after careful evaluation, which included inpatient observation and complete medication washout in most cases. These estimates put the approximate incidence to be about 1/300th of the adult-onset illness.

Natural History, Prognostic Factors, and Outcomes

Most reports on the natural history and course of COS come from the NIMH longitudinal study of COS.

Since 1990, children with early-onset psychosis have been recruited nationally for diagnostic screening for COS at the NIMH. Diagnosis of COS is confirmed after an extensive evaluation, which includes inpatient observation during a 3-week drug washout period. To date, 118 patients have participated in the study, including 43 boys and 31 girls with a mean age of 14.06 ± 2.67 years and mean age of onset of psychosis at 10.07 ± 1.9 years. Once the diagnosis is confirmed, a structural brain MRI scan is obtained with prospective re-scans at 2-year intervals.

The general outcome remains poor with most COS children continuing to show residual symptoms: both cognitive deficits and/or psychotic symptoms. In a recent analysis, at 2-year follow-up, almost 75% of COS patients still reported either positive or negative residual symptoms (Greenstein et al. 2008). The clinical course, in general, tends to be non-episodic (unlike that for the adult illness), chronic, and treatment refractory with most children ending up on clozapine (discussed under treatment).

Although there are no specific factors that can be detected in COS either during the premorbid or prodromal course of the illness, however, many features are more striking compared to the AOS during this period which are described under pathophysiology.

Clinical Expression and Pathophysiology

Premorbid Development

A striking phenomenological feature of COS relative to adult-onset schizophrenia appears to be the higher rates of early language, social, and motor developmental abnormalities, possibly reflecting greater impairment in early brain development. In the NIMH sample, premorbid development is defined as development prior to 1 year before psychosis onset and assessed using the Cannon-Spoor Premorbid Adjustment Scale (PAS) (Cannon-Spoor et al. 1982) and the Hollis premorbid development scale (Hollis 1995); social and speech and language impairments were the most common abnormal features in COS, which was also observed by four other

independent research centers (Alaghband-Rad et al. 1995; Asarnow and Ben-Meir 1988; Gogtay et al. 2004b; Green et al. 1992; Hollis 1995; Nicolson et al. 2000; Russell et al. 1989; Watkins et al. 1988).

Risk Factors

Obstetric Complications

An analysis comparing the obstetric records of 60 COS children and 48 healthy siblings using the Columbia Obstetrics Complication Scale (Malaspina 2003), a comprehensive measurement scale consisting of 37 variables, did not find higher incidence of obstetric complications in COS patients compared to the healthy sibling control group (Ordóñez et al. 2005).

Eye Tracking

Smooth pursuit eye movement (SPEM) disorders have been reported in 25–40% of first-degree relatives of schizophrenic probands (Holzman 2000), and other studies have suggested more striking in COS than in AOS with a bilineal pattern of inheritance (Ross et al. 1999). In a recent analysis, we compared 70 COS parents, 64 AOS parents, and 20 COS siblings to separate matched control groups and found that the effect sizes for SPEM abnormalities were higher for COS than for AOS relatives, indicating that genetic factors underlying eye-tracking dysfunction may be more salient for COS (Sporn et al. 2005b).

Familial Schizophrenia Spectrum Disorders

Schizophrenia spectrum disorders consist of schizophrenia and schizoaffective disorders on Axis I and schizotypal, paranoid, and schizoid personality disorders on Axis II (Asarnow and Ben-Meir 1988). A prior study by Asarnow et al. showed higher rates of schizophrenia spectrum diagnoses for COS relatives than for relatives of probands with attention deficit hyperactivity disorder or community controls (Asarnow et al. 2001). Similarly, as expected in our recent analyses of parental diagnosis in 97 parents of COS probands, 97 parents of AOS probands, and matched community controls, it was also found that rate of schizophrenia spectrum disorders was

higher in COS than in AOS, and both were higher than community controls supporting the continuity between COS and AOS, and more salient familial genetic risk in COS (Nicolson et al. 2003).

Familial Neurocognitive Functioning

Cognitive abnormalities, executive functioning, short-term memory, and language function are well documented as endophenotypic measures for family members in AOS (Egan et al. 2001). Particularly striking have been the decreased performance on the Trail Making Test part B (Keefe et al. 1994) and digit span (Tuulio-Henriksson et al. 2002). When we compared neuropsychological deficits in 67 parents and 24 full siblings of COS probands in comparison with matched community controls for Trail Making Tests A and B and Wechsler Intelligence Scale-Revised Digit Span and Vocabulary, COS siblings performed significantly poorer than community controls although the rates of neuropsychological abnormalities for COS were not significantly higher than for AOS (Gochman et al. 2004).

Pervasive Developmental Disorder and COS

Frequently, the diagnosis of autism or pervasive developmental disorder (PDD) has been raised early in the development in our cases, and some studies have claimed that autism per se might be a risk factor for later psychosis (Cantor et al. 1982; Clarke et al. 1989; Petty et al. 1984). In the two large studies examining this systematically, COS is preceded by and comorbid with pervasive developmental disorder in 30–50% of cases. Epidemiologic and family studies also find association between the disorders, and both disorders have evidence for accelerated trajectories of anatomic brain development at ages near disorder onset, and a growing number of shared risk genes and/or rare small chromosomal variants (micro-deletions or duplications). Thus, core neurobiological processes are likely common for subsets of these two heterogeneous clinical groups.

Neurocognitive Functioning in COS Probands

Neuropsychological function in COS has been studied in depth by Robert Asarnow and

colleagues (Asarnow 1999; Asarnow et al. 1994, 1995). While rote language skills and simple perceptual processing are not impaired, these children perform poorly on tasks involving fine motor coordination, attention, and short-term and working memory (Karatekin and Asarnow 1998). Evoked-potential studies show diminished amplitude of brain electrical activity during these tasks suggesting that allocation of necessary attentional resources is deficient, which is also shared by schizophrenic adults (Asarnow et al. 1995). It is generally established for adult schizophrenia that cognitive function deteriorates at onset of psychosis but remains stable afterward (Goldberg et al. 1993; Russell et al. 1997). Our earlier study had shown that COS children ($n = 27$) as well as MDI children ($n = 24$) share similar deficits in attention, learning, and abstraction that resembled the pattern in adult patients with schizophrenia (Kumra et al. 2000). In a recent analysis on 71 COS probands where preadmission IQ data were also available from medical and school record ($n = 27$), post-psychotic cognitive function (defined as >3 years of onset) for up to 8+ years was studied. As expected, all COS patients scored significantly below age norms, but for 46 COS patients seen systematically for follow-up, there was no post-psychotic IQ decline. Thus, in spite of greater severity and generally poor clinical outcome, there was no evidence of a longer-term degenerative cognitive process in COS (Gochman et al. 2003).

Comorbid Disorders

Comorbid psychiatric disorders, particularly DSM-defined mood and anxiety disorders, often coexist with schizophrenia (Bermanzohn et al. 2000; Green et al. 2003; Huppert and Smith 2005), although the hierarchical system for DSM limits independent diagnoses of comorbidities (Bermanzohn et al. 2000), and these disorders may often be part of (or masked by) the symptoms of the primary illness. Alternatively, it is often assumed that symptoms such as severe anxiety are the result of underlying schizophrenic process and that depressive symptoms are almost inevitable in schizophrenia; thus, the diagnoses of independent Axis I conditions are often ignored

(Bermanzohn et al. 2000). However, recent studies indicate that psychiatric comorbidities can significantly alter the presentation, clinical course, or prognosis of the illness, and thus, accurate diagnoses of comorbidities could have useful implications for disease outcome (Fenton and McGlashan 1986; Huppert et al. 2001). As no prior studies have reported comorbidities for childhood-onset schizophrenia (COS), we analyzed the prevalence of comorbid Axis I diagnoses in 76 COS cases at the time of first NIMH admission, and at 4-year follow-up ($n = 28$), and correlated the comorbid diagnoses with age of onset of psychosis, clinical ratings of illness severity, familiarity for schizophrenia spectrum disorders, and early premorbid development.

As has been seen with AOS, the most frequent comorbid diagnosis at NIMH screening was depression (54%) followed by obsessive-compulsive disorder (OCD; 21%), generalized anxiety disorder (GAD; 15%), and attention deficit hyperactivity disorder (ADHD; 15%). The rate of "any" anxiety disorder (GAD, OCD, separation anxiety, PTSD, and panic disorder combined) at screening was 42%. Diagnosis of comorbid depression correlated with poorer global assessment of severity (GAS) scores, and presence of an anxiety disorder only predicted anxiety at 4-year follow-up. No other Axis I diagnoses showed correlations with any clinical measures, and there were no significant associations between comorbid diagnoses and IQ, familiarity, medication status, premorbid functioning, or age of onset at psychosis. Interestingly, there was no "current" comorbid depression at the 4-year follow-up visit, possibly due to our high use of antidepressant treatment (45%). However, the rates of anxiety disorders did not change much at the 4-year follow-up, despite adjuvant anxiety medication use, suggesting either refractory nature of these conditions or their close association with schizophrenia pathology.

Cortical Development in COS

Morphometric studies of COS populations have provided unique insights into schizophrenia brain development. Initial COS studies using whole lobe volumetric measures showed profound and

global GM loss with ventricular expansion in COS (Gogtay 2008; Rapoport et al. 1997, 1999; Rapoport and Inoff-Germain 2000). With novel neuroimaging methodology, finer-scale brain mapping on the longitudinal data revealed that the GM loss in COS had a characteristic back-to-front (parieto-frontal-temporal) pattern of spread during adolescent years (Thompson et al. 2001) which appears to be an exaggeration of the healthy GM developmental pattern (Gogtay et al. 2004a), perhaps reflecting lack of inhibitory controls on the normal maturational GM loss (Schoop et al. 1997; Sowell et al. 2001). As the children mature and become young adults, the GM loss appears to slow down and get circumscribed to prefrontal and temporal cortices and merging into the adult schizophrenia pattern (Greenstein et al. 2006), establishing the neurobiological continuity between the two counterparts of the illness.

The GM deficits in schizophrenia may reflect a disease process that is pronounced earlier in the illness and/or at an earlier age, perhaps reflecting a stronger genetic vulnerability interacting with the early brain developmental windows (Pantelis et al. 2003) and exaggerated (dysregulated) neurodevelopment (Lieberman 1999; Lieberman et al. 2005; Woods 1998). It is also possible that the structural GM differences are most dynamic in the first years around psychosis onset and then vary with the illness over time perhaps influenced by other environmental or illness-related factors such as medication exposure. Indeed a similar pattern of brain changes has also been tracked as psychosis develops in those at risk (Pantelis et al. 2007).

The diagnostic specificity of the GM trajectories was explored by comparing individuals with COS and children who were “ruled out” as having schizophrenia (Kumra et al. 1998). A surprising 40% of those followed longitudinally from this group converted to bipolar I disorder and had pre-onset scans. The developmental trajectories for bipolar I children (with psychosis) showed a subtle but distinct pattern of cortical GM gain in left temporal cortex and loss in right temporal and bilateral subgenual cingulate cortices, pattern that has no overlap with that seen for COS (Gogtay et al. 2007b). These observations point toward

diagnostic specificity of the GM findings in COS (Gogtay et al. 2007a; b). These studies still do not address the effects of medications on “longitudinal” GM trajectories, but a recent analysis comparing GM development between COS subjects treated with clozapine and those with olanzapine showed no differences in GM trajectories (Mattai et al. 2010). Further studies are needed correlating medication exposure as a continuous measure with brain development, or on unmedicated subjects to address this question.

GM abnormalities in schizophrenia may be, at least in part, familial/trait markers (Cannon et al. 2003; Gilbert et al. 2003; Weinberger and McClure 2002; Yucel et al. 2003). We have extended this question in our studies to ask whether GM “trajectories,” rather than deficits, are endophenotypes, indicting dysregulation of development as the crucial defect. Longitudinal GM findings in 52 healthy full siblings of COS patients showed initial cortical GM deficits which not only did not progress during adolescence (unlike their COS probands) but normalized by age 20. A recent analysis using 47 non-overlapping healthy siblings matched with 48 non-overlapping healthy controls replicated these findings (Mattai et al. 2011). Several inferences can be drawn from these findings. First, the pattern of “improving GM deficits” and the localization to “prefrontal and superior temporal areas” in both COS probands and siblings point toward overall similarities in the patterns of GM development in both groups where healthy siblings show a more time limited “shift to the left” compared to the COS probands (earlier deficits which are corrected before adulthood). Second, this points to protective/restitutive factors in sibling brain development, which could relate to functional outcome (Gogtay et al. 2007a). Finally, absence of parietal deficits in healthy siblings may indicate that parietal deficits require a nongenetic trigger as supported by twin studies of adult-onset cases (Cannon et al. 2002).

The profound GM loss in COS could, in theory, be only a perceived loss resulting from the encroachment of continued white matter growth, a process that extends through at least the fourth decade (Benes 1993; Benes et al. 1994; Sowell

et al. 1999). New findings using tensor-based morphometry (TBM) showed that COS patients actually had up to 2% slower WM growth rates per year than healthy controls ($p = 0.02$, all p -values corrected), with greater effect sizes in the right hemisphere ($p = 0.006$) (Gogtay et al. 2008); thus, progressive GM deficits seen in COS do not appear secondary to WM growth (Gogtay 2008).

Genetic Studies

While rare copy number variants (CNVs) have been found to be increased for our COS population (Walsh et al. 2008), only two variants (16p11.2 and 22q11) have shown a unique anatomic brain profile (McCarthy et al. 2009; Usiskin et al. 1999). Recently, genome-wide expression analyses of brain tissue from varied postnatal ages indicated that schizophrenia susceptibility genes are overrepresented during frontal cortical development (Choi et al. 2009; Harris et al. 2009; Webster et al. 2010; Wong et al. 2009). However, given the large number of weak genetic and environmental risk factors and increasing evidence for the dimensional nature of psychosis (Polanczyk et al. 2010), it seems more and more likely that schizophrenia represents a continuum of risk involving many factors. For example, a recent population study found a ninefold risk of schizophrenia if the presence of a parent with psychosis was combined with maternal depression during pregnancy (Maki et al. 2010). Other studies have documented other gene-environmental interactions such as that between genetic risk and urban birth (van Os et al. 2004).

Evaluation and Differential Diagnosis

COS is difficult to diagnose as symptoms of psychosis appear very early in a child's life and are difficult to tease apart from other childhood phenomena such as normal imaginative play, behaviors generated by situations or due to secondary gain. Hallucinations are not uncommon in otherwise healthy children although they tend to be more serious in school-age children (Polanczyk et al. 2010; Poulton et al. 2000).

The disorders most commonly misdiagnosed as childhood-onset schizophrenia are:

1. Severe anxiety can lead to hallucination in children.
2. Affective disorders: Hallucinations are relatively common in pediatric bipolar disorder and major depression (Chambers et al. 1982; Varanka et al. 1988). However, the psychotic symptoms in these conditions tend to be mood congruent, and follow-up studies on this population generally suggest a stable clinical outcome (Garraalda 1984a; McClellan and McCurry 1999; McClellan et al. 1999; Ulloa et al. 2000).
3. Organic psychosis and substance abuse disorders (may mimic withdrawal states or negative symptoms) (Caplan et al. 1991; Garraalda 1984b).
4. Pervasive developmental disorders and childhood disintegrative disorder.
5. Children with conduct disorder and various other behavioral disturbances can show hallucinations (Garraalda 1984a, b).
6. The atypical psychosis group provisionally labeled as "multidimensionally impaired (MDI)" is an important differential diagnosis. These patients are characterized by brief, transient episodes of psychosis and perceptual disturbance, typically in response to stress, emotional lability disproportionate to precipitants, cognitive deficits as indicated by multiple deficits in information processing, no clear thought disorder, and high comorbidity with ADHD. This group of patients is not adequately characterized by existing DSM-IV categories (Kumra et al. 1998; McKenna et al. 1994; Towbin et al. 1993), and in DSM, these patients would be considered as psychosis NOS.

The psychosis of childhood-onset schizophrenia can usually be distinguished by its severe and pervasive nature and its non-episodic, unremitting course (Nicolson and Rapoport 1999). Additionally, these children show poorer premorbid functioning in social, motor, and language domains, learning disabilities, and disruptive behavior

disorders (Alaghband-Rad et al. 1995; Green et al. 1992; Hollis 1995), and although not reported in studies of the premorbid history of adult-onset schizophrenia (Done et al. 1994; Jones et al. 1994), transient autistic symptoms such as hand flapping and echolalia occur in toddler years for a substantial minority of the children (Alaghband-Rad et al. 1995; Russell et al. 1989), probably reflecting compromised early brain development.

Treatment

Although rare, childhood-onset schizophrenia is a devastating disorder, which is frequently resistant to treatment, and unfortunately, there is a narrow evidence base to guide treatment, particularly as there are no trials comparing atypical antipsychotics, which have become the mainstay of current treatment. Two prior randomized controlled trials established the superiority of typical antipsychotics over placebo in COS (Pool et al. 1976; Spencer and Campbell 1994), but only one trial had compared the efficacy and safety of two antipsychotics, demonstrating the therapeutic superiority of clozapine over the typical antipsychotic haloperidol (Kumra et al. 1996). As a result of our prior study and studies in AOS patients (Davis et al. 2003; Moncrieff 2003), clozapine has established itself as the de facto gold standard in studies establishing antipsychotic efficacy – particularly in a pediatric population.

Our recent double-blind randomized controlled trial of comparing clozapine ($n = 12$) with olanzapine ($n = 13$) showed that clozapine was associated with a significant reduction in all outcome measures, whereas olanzapine showed significant improvement only in measures of negative symptoms and in the BPRS. A direct comparison of treatment efficacy showed a significant advantage for clozapine in the alleviation of negative symptoms of schizophrenia (producing a 4% greater reduction in SANS, $p = 0.04$, effect size 0.89), which was not correlated with improvement in mood or extrapyramidal side effects. Clozapine was, however, also associated with more overall side effects, including enuresis, tachycardia, and hypertension. By 2-year follow-up,

15 patients were on clozapine, and there was evidence of sustained clinical improvement, but additional side effects emerged including lipid anomalies ($N = 3$) and seizures ($N = 1$). Both treatments were associated with marked weight gain. This study suggests that clozapine should be the drug of choice in treatment-resistant childhood-onset schizophrenia (Shaw et al. 2006).

Adverse Effects of Clozapine

Clozapine, which is a lifeline for many of the COS children, is associated with several side effects. The NIMH study has started addressing the question of how to manage these side effects so that these children can continue to stay on clozapine.

Neutropenia and Akathisia

Children and adolescents treated with clozapine have increased susceptibility to neutropenia. This can be successfully managed by addition of lithium (Sporn et al. 2003). Similarly, akathisia seen only rarely in adults on clozapine appears more common in children (6 out of 15 children recently treated with clozapine had developed akathisia) and can frequently manifest as worsening of psychotic symptoms or agitation in children, which frequently results in dosage increment. This side effect is responsive to adjunctive propranolol (Gogtay et al. 2002) treatment.

Weight Gain

Weight gain is a significant effect of atypical antipsychotics and is more pronounced in children and adolescents than in adults (Ratzoni et al. 2002). Genetic risk for weight gain on atypical antipsychotics has been suggested (polymorphism in beta3 and alpha 1A adrenergic, 5-HT2C and histamine receptors, and TNF-alpha) (Basile et al. 2001), and a number of biochemical correlates or predictors of weight gain have been reported in the literature (leptin, prolactin, triglyceride, and HDL levels).

In our recent analysis of 23 patients treated with clozapine who had at least one medication-free week, plasma levels of hormones putatively involved in weight and appetite regulation (leptin, insulin, ghrelin, adiponectin, amylin, TNF-alpha) were compared with age, sex, and BMI-matched

healthy controls. After 6 weeks on clozapine, COS children showed increases in BMI ($p = 0.001$) and leptin ($p = 0.01$). For COS patients, BMI at baseline and week 6 correlated with insulin level ($r = 0.5, p = 0.004$). In addition, increase in BMI was positively correlated with clinical improvement in CGI, SAPS, and SANS rating scales ($p < 0.05$). Our findings suggest that clozapine-induced weight gain may be associated with increased leptin, reduced adiponectin and ghrelin, and clinical improvement (Sporn et al. 2005a).

Childhood-Onset Pervasive Developmental Disorder

Michele Villalobos

The Edward Zigler Center in Child Development and Social Policy, Yale Child Study Center, New Haven, CT, USA

Synonyms

[Pervasive developmental disorder not otherwise specified](#); [Pervasive developmental disorders](#)

Definition

The term childhood-onset pervasive developmental disorder (COPDD) was originally used in the DSM-III. The essential features of COPDD are profound disturbance in social relations and multiple oddities of behavior all developing after 30 months of age and before 12 years (American Psychiatric Association [APA] 1980). This category was intended to capture the children who presented with features of pervasive developmental disorders but developed the disorder after 30 months of age. In the DSM-III-Revised, the category was removed and the category pervasive developmental disorder not otherwise specified (PDDNOS) was added. PDDNOS now refers to those children who do not meet the criteria for a specific pervasive developmental disorder but demonstrate features.

Definition

Foster care is a system in which children, youth, and young adults are temporarily placed outside of their birth family's home. The state maintains oversight of this child-focused system through the involvement of the courts and child protection service agencies. Increasingly, most states have recognized that group care, in which young people are placed in group homes or in a residential setting, is not the best option for youth in need of out-of-home care. As such, other options, such as family care or kinship care and foster parenting, have undergone extensive and robust development and have been fairly widely utilized in various states. The general types of foster care include family/kinship care where the youth is placed with someone related by biology or marriage, placement in emergency shelters, traditional county-level foster care (placement with a certified foster parent in their home), therapeutic foster care (placement with certified foster parents in their home with therapeutic and skill development activities built in), group homes which are within a community setting, and residential placements which offer the highest level of structure and are typically located in a more secure campus-like setting. Residential-based services sometimes include diagnostic settings to help assess treatment options and the development of a youth's individualized program (VanBergeijk and McGowan 2001). The reasons for removal from the family home can include various types of abuse and neglect which frequently may, but do

not always, result in the termination of parental rights. In these cases, guardianship may shift to a relative or to the local department of social services. The type of foster care placement is often impacted by the availability of appropriate placements and is determined by the needs of the specific youth. The primary purpose of foster placement is to provide safety for the youth removed from their family's home. Once in the foster care system, safety, well-being, and permanency are the primary goals typically.

Historical Background

In 1853, Charles Loring Brace founded the Children's Aid Society (CAS) in New York City. The purpose of the CAS was to provide education and housing for homeless youth due to his personal concern over the number of youth who engaged in begging and stealing due to the lack of appropriate living conditions (Ramsey 2007). The Department of Health and Human Services held the first White House conference on the Care of Dependent Children in 1909. Prior to this conference came the creation of the Children's Bureau to oversee the practices "pertaining to the welfare of children and child life among all classes of our people." The establishment of the Children's Bureau led to the standardization of practices governing foster care. In 1974, the Child Abuse Prevention and Treatment Act (CAPTA) of 1974, P.L. 93–247, was passed. The purpose of this law was "to provide financial assistance for a demonstration program for the prevention, identification, and treatment of child abuse and neglect." Subsequently, it was revised in 1978 to help promote healthy development and free individuals for adoption. Since the initial passing of P.L. 93–247, much additional legislation has been passed in the United States dealing with child protection, including the reauthorizing and amending of CAPTA several times, most recently in 2010, and the Preventing Sex Trafficking and Strengthening Families ACT, P.L. 113–183 in 2014. For a full historical account of relevant legislation, see <https://cb100.acf.hhs.gov/childrens-bureau-timeline>.

Foster Care and Autism

Every decade, a federally mandated study is conducted on abuse and neglect to identify the incidence, both reported and unreported, of abuse and neglect of children. The fourth such study, conducted in 2010, covering years 2005–2006 indicated that almost 3 million children (1 in 25) were endangered, with 1.25 million of those experiencing within this time period http://www.acf.hhs.gov/sites/default/files/opre/nis4_report_exec_summ_pdf_jan2010.pdf. Of that number, 29% experienced abuse as opposed to the remainder who experienced neglect. Of those neglected, approximately 72% were either educationally or emotionally neglected. According to the Department of Health and Human Services, there has been a decreasing trend in the number of youth in foster care leading up to 2005, when the number of youth placed out of home was approximately 511,000. Between 2017 and 2018, there was a decrease of approximately 3,388 youth (<http://www.acf.hhs.gov/sites/default/files/cb/afcarsreport26.pdf>). In 2018, the number of youth estimated to be in out-of-home foster care was 437,283.

The estimated number of youth with intellectual and developmental disabilities (IDD) in foster care nationally ranges from 28% to more than 50% (Lightfoot et al. 2011; Ringeisen et al. 2008). With over 30% of the children currently in foster care aged 3 years or younger, identification of developmental delays and early intervention services is critical to the well-being of children within the foster care system (US Department of Health and Human Services 2019). Although children raised in residential foster care display fewer social deficits and ASD symptoms than children raised in institutional settings (Levin et al. 2015), young children enter the child welfare system with significant developmental needs that often are not properly addressed (Casanueva et al. 2008). Systematic screening of all children in the foster care system performed by caregivers can increase the identification of developmental disabilities, including autism among foster care youth (Jee et al. 2010). Screening by developmental pediatricians and other medical

professionals who work with youth in foster care is also critical to identification of autism and improving opportunities for appropriate treatment.

Even when autism is identified, youth with autism spectrum disorders (ASD) are at a much greater risk for poor outcomes and greater lengths of stay in the foster care system (Bilaver and Havlicek 2013). One important contributor to poor outcomes is that individuals in foster care have increased exposure to adverse childhood experiences (ACEs) such as being abused, repeatedly witnessing violence against others, or other forms of trauma. Berg et al. (2016) found that having autism in childhood can in itself be significantly associated with a high number of ACEs. To add to this fact, the impact of foster care plus ASD places these youth at a much higher risk for exposure to ACEs. Youth with autism may be at an even greater risk, for example, for physical abuse, a prominent ACE, as compared to peers with other disabilities and peers without disabilities. The findings of Berg et al. (2016) are consistent with the findings for other children with communication difficulties (Sullivan and Knutson 1998). According to the Centers for Disease Control and Prevention (CDC; Felitti et al. 1998), these experiences are major risk factors for illness, death, social problems such as challenging behavior (e.g., aggression, self-injury), and disability. Similarly, scientists at the Center for the Developing Brain found that ACEs and their associated risk factors have serious implications for disruptions in brain development, particularly when experienced early in life. These disruptions to development may lead to difficulties with emotional regulation and attention difficulties, among other challenges (Center on the Developing Child 2012). The combined risk factors of ASD and ACEs can make the outcomes for these youth quite poor, particularly if they do not receive appropriate assessment or care (Kerns et al. 2015; Simms et al. 2000). Of additional concern for individuals with ASD is the likelihood that these youth may be placed into foster care placement not due to abuse and neglect but rather due to inability of the biological parent(s) to provide adequate support and care given the significant

challenges that parents of youth with ASD face (e.g., challenging behavior) (Estes et al. 2009). Other risk factors attributed to the concomitant impact of both ASD and foster care placement are the number of transitions between homes and providers due to externalizing behaviors (e.g., aggression), which are significant risk factors for placement disruptions. These behaviors may occur at an even higher rate than typical for persons with autism as a result of experiencing frequent transitions in living arrangements due to the difficulty many individuals with ASD have with transitions (Barber et al. 2001). Individuals in foster care often transition between home, community, and residential care settings with some frequency. In fact, data from 2010 revealed that 14.9% of children experienced at least three out-of-home placements in less than a year (Children's Bureau, Administration for Children and Families, US Department of Health and Human Services 2012).

An additional concerning factor affecting foster placement stability for individuals with autism may be the lack of expression of emotion and difficulties with communication between the foster child and foster parent/caregivers (Bernedo et al. 2015). Foster parents typically are motivated to provide care because they believe they are making a difference. When a child can express themselves through words and can show displays of affection toward the foster parent, often the relationship blossoms, and the mutual commitment strengthens. Given communication and expression of emotions are common concerns for individuals with ASD, foster parents may frustrate more easily and may not experience the same level of gratification as with "typical youth." For this, and other reasons (e.g., challenging behavior), foster parents may choose to disrupt the placement more often than with individuals with autism. Finally, placement disruptions, which are highly problematic for all children in care, may be exacerbated by issues affecting individuals with autism. Specifically, issues with change, need for consistency, and the need for sameness/routine can have a significant effect on an individual both emotionally and behaviorally in all settings but particularly when the stability of placement is

so tenuous. For example, placement disruptions can impact an individual's academic performance, with a loss of 4 months of instruction for every move (Mehana and Reynolds 2004). Coupling this with the difficulty individuals with ASD often have with changes in their environment, there is likely to be a significantly greater impact on their functioning.

Future Directions

One way to mitigate the impact of these traumatic experiences for individuals with ASD is to provide permanency (i.e., stable foster placement, adoptive placement, or return to biological family with necessary supports). Given the particular difficulties with transitions that youth with ASD experience, finding a stable placement may be especially important; however, according to Cooley et al. (2015), challenging behaviors, such as those displayed by individuals with ASD, can lower foster parents' satisfaction and motivation to continue to provide care, leading to changes in placement. Adding to this, the particular difficulty of youth with autism to communicate their needs and to display affection to a foster parent, successful placement and stability may be elusive for many individuals with ASD.

Targeted resources and programming must be built into the significantly overtaxed foster care system to both prevent the need for foster care placement and ensure the successful placement and, whenever possible, reunification with the child/youth/young adult's birth family. First, it is critical to teach Departments of Social Services (DSS) case workers who first come into contact with families in need to recognize the signs and needs associated with a diagnosis of ASD and ACEs. This is important to identify in both parents and the youth. Undiagnosed developmental concerns in a parent can lead to challenges in raising a child, particularly one who also has a developmental disability, such as ASD. Furthermore, research suggests that children of mothers who have experienced a high level of ACEs (>3) were 2.2 times more likely to have developmental delay (Folger et al. 2018). Understanding the

needs of the birth parents is critical in promoting support for reunification and obtaining the appropriate services for the family. Additionally, identification of ASD symptoms in the youth may be critical in ensuring the right services are obtained when removing the youth from their home.

Other services that may be critical include access to quality medical care and diagnostics (e.g., to accurately diagnose ASD and/or co-occurring mental health concerns); parent training for both birth parents and foster parents (e.g., Bearss et al. 2015); linkages with early intervention resources, educational resources, and/or vocational resources; and placement in a highly trained therapeutic foster care home when appropriate. Access to evidence-based clinical tools to assess trauma and ACEs in people with ASD do not yet exist (Fuld 2018; Berg et al. 2016). However, using assessment scales to evaluate ACEs like those used by Berg et al. (2016) could be useful in evaluating trauma and guiding treatment.

Access to evidence-based treatments for individuals with ASD in foster care are unfortunately often minimal or nonexistent, including access to applied behavior analysis (ABA) services. Additionally, evidence-based treatments for trauma in children, youth, and young adults such as cognitive behavior therapies (e.g., TF-CBT, DBT) must be evaluated for use with individuals with ASD to mitigate the effects of exposure to adverse childhood events.

Children's Communication Checklist (CCC-2)

Dorothy Bishop
Department of Experimental Psychology,
University of Oxford, Oxford, UK

Synonyms

CCC-2; [Children's communication checklist, version 2](#)

Description

The Children's Communication Checklist (CCC-2) is a checklist that is used to assess aspects of everyday communication that are difficult to evaluate using traditional language tests. It consists of 70 items divided into 10 subscales and is usually completed by a parent or other

caregiver, though useful information can be provided by teachers or other professionals who know the child well. It takes between 5 and 15 min to complete.

The ten scales are:

- A. Speech
- B. Syntax
- C. Semantics
- D. Coherence
- E. Inappropriate initiation (initiation in US version)
- F. Stereotyped language (scripted language in US version)
- G. Use of context
- H. Nonverbal communication
- I. Social relations
- J. Interests

The first four scales, A to D, assess aspects of language structure, vocabulary, and discourse. These are all areas that are often impaired in non-autistic as well as autistic children with language impairments.

The next four scales, E to H, cover aspects of communication that are not easy to assess using conventional language assessments but which are often impaired in children with autistic spectrum disorders.

The last two scales, I and J, assess behaviors that are usually impaired in cases of autistic spectrum disorder.

For each scale, there are seven items, five describing difficulties and two describing strengths. The first 50 items focus on children's difficulties, with items from different scales interleaved, and the last 20 items describe children's strengths. For each item, the respondent completes a rating reflecting the frequency with which a behavior is observed.

- Less than once a week (or never)
- At least once a week, but not every day
- Once or twice a day
- Several times (more than twice) a day (or always)

Uses of the CCC-2

The CCC-2 can be used in three ways:

1. To give a quantitative estimate of pragmatic language impairments in children.
2. To screen children for risk of language impairment. Those identified as at risk can then be referred for more detailed language assessment.
3. To help identify children who may merit further assessment for an autistic spectrum disorder. It is important to stress that CCC-2 cannot be used to diagnose autistic disorder; however, a finding of low scores on scales E to H, plus evidence of impairment on scales I and J, indicates that a more detailed diagnostic evaluation for autism is merited.

Application and Availability

Norms are available for both UK and US standardization samples over the age range 4–16 years. Both UK and US versions are published by Pearson Publishing. An electronic scorer comes with the checklist and is recommended as manual scoring is complex.

Some of the items in the CCC-2 are not suitable for describing adult communication. A modification of the CCC-2, the CC-A, was therefore developed and normed for adults in 2009.

In addition, a self-report version, CC-SR, suitable for literate teenagers and adults was developed in 2009, with UK norms.

Historical Background

Checklist for Language-Impaired Children (CLIC and CLIC-2)

CCC-2's origins were in CLIC, a research instrument that was devised as a means of identifying from within a language-impaired sample those children with a clinical picture of "semantic-pragmatic disorder." This subgroup had been described clinically, and included children who spoke in long and fluent sentences but whose use of language was strange. Utterances may be tangential, off-topic, or long and rambling. The original CLIC had 20 multiple-choice items, with the respondent selecting which of five descriptions best described the child. CLIC was piloted with teachers and therapists but was found to be unsatisfactory because respondents

often felt none of the provided options described the child. Accordingly, the format was revised to create CLIC-2 in which each item described a single communicative behavior which was rated as "applies definitely," "applies somewhat," or "does not apply."

A large-scale reliability study with CLIC-2 was conducted at special schools for language-impaired children using ratings by teachers and therapists. This too was not entirely satisfactory, with inter-rater reliability being low for some items.

The Children's Communication Checklist: Original Version

The original Children's Communication Checklist was developed from CLIC-2 by selecting those items with highest inter-rater reliability and grouping these into new scales on the basis of statistical criterion of internal consistency. This gave a checklist with nine scales: A, speech; B, syntax; C, inappropriate initiation; D, cohesion; E, stereotyped conversation; F, use of context; G, rapport; H, interests; and I, social interaction.

A validation study was conducted with the CCC using a subset of children who had participated in a national study of language-impaired 7-year-olds. Their teachers and therapists completed CCCs independently for the same children, making it possible to assess inter-rater agreement. Inter-rater reliability varied from scale to scale but was good for a pragmatic composite and reasonable for other scales. The distribution of CCC ratings also differentiated children who were categorized on clinical grounds into cases of definite, possible, or no semantic-pragmatic disorder.

Up to this point, the CCC was used only to subclassify children already known to have a communication impairment. However, there was growing interest in its potential in a broader context, both as a screening tool for language and communication problems and as a means of identifying pragmatic difficulties in children with psychiatric impairments. In addition, there seemed to be potential to extend data on the CCC to a broader age range and to explore whether it would yield valid data with parents as respondents.

To consider these questions, a further study with the CCC was carried out in collaboration with Dr. Gillian Baird, a developmental pediatrician at a tertiary referral center in London, with results being published in 2001. CCC data were gathered from a sample of children aged 5–16 years who were referred to the center for diagnostic assessment. Two copies of the CCC were sent to parents with their letter of appointment, and they were asked to have the child's teacher or therapist complete one copy and to complete the other themselves. In addition, CCC data were collected from 31 typically developing children. Agreement between parent and teacher ratings was only modest ($r = 0.45$), but both sets of ratings showed association with the child's clinical diagnosis, with the parent ratings giving particularly strong association. Scores for the typically developing children showed little overlap with those from the clinical sample, suggesting that the CCC might be useful as a means of screening for communication problems in general as well as of identifying pragmatic difficulties. In addition, this study indicated that children with a diagnosis of autism obtained very low scores on the CCC overall.

Development of CCC-2

When CCC had been in use for a few years, it was decided to develop a new version of the checklist for standardization in the UK. One major change between CCC and CCC-2 was in the response format. It was decided that a more concrete rating of frequency of observing a behavior would be less subjective and easier to use than the original response options. The CCC-2 also had the same number of items for all of the scales and gave more emphasis to items assessing non-pragmatic aspects of communication such as speech and syntax. Tables are provided to transform raw scores on each scale to age-scaled scores with mean 10 and SD 3. CCC-2 also provided norms for two composite scores. The first, the General Communication Composite, is based on all the communication scales (A to H). This is effective in discriminating children with *any* clinical diagnosis from typically developing children. The second index, the Social Interaction Deviance

Composite, is an index of mismatch between structural and pragmatic/social skills. This was derived to give optimal discrimination between children with typical SLI and those with evidence of pragmatic difficulties. A low SIDC is seen when a child has intact structural language skills but major pragmatic difficulties. This kind of profile was characteristic of children with a diagnosis of Asperger syndrome.

CCC-2, US version

A US version of CCC-2 was subsequently standardized and was published in 2006. Changes to the checklist itself were minor and just involved alteration of wording to make it more suitable for the US context. The scoring, however, was altered so that the General Communication Composite was scaled with a mean of 100 and SD of 15. It is not therefore comparable to the UK version, which is based on the sum of eight subscales, with expected mean of 80. In addition, some changes were made to the names of scales. The SIDC was renamed the Social Interaction Difference Score (SIDI).

Psychometric Data

The UK version of CCC-2 was standardized on a sample of 542 children aged 4–16 years, which was broadly representative of the socioeconomic distribution of the general population and covered a wide geographic range (though not all regions were represented). Before deriving norms, responses were inspected to find cases where the pattern of responses suggested poor comprehension of instructions; rules were specified to identify these, and they were excluded. Floor effects were obtained on all scales, especially at the older ages (i.e., many children had no evidence of impairment). Norms were derived for each scale from a regression equation that predicted total log score from log age in months. These scores were scaled to mean of 10 and SD of 3. Because of the non-normality of the data, the scaled scores have a ceiling, which means that CCC-2 is not well suited for assessing variations among children who have above-average communication skills.

The test manual reports internal consistency and inter-rater agreement for all scales. Coefficient alpha (internal consistency) was 0.65 or more for all scales. Inter-rater reliability between a parent and a professional (teacher or speech-language therapist) was not impressive for individual subscales. The inter-rater reliability for the General Communication Composite (GCC) was 0.396, and for the Social Interaction Deviance Composite, it was 0.790. Disagreement between parent and professional ratings generally took the form of professionals rating a lower level of impairment.

Validity was assessed using a sample of children with diagnoses of specific language impairment (SLI), pragmatic language impairment (PLI), and high-functioning autism (HFA) or Asperger syndrome as well as twenty typically developing (TD) children. There were striking differences between the clinical groups and the TD group on all ten subscales. On the GCC, there was little overlap between the distribution of scores of the clinical groups and the TD group. However, the GCC did not differentiate well between the different types of disorder. Rather, it acted as a general indicator that the child had communication difficulties. The groups were better differentiated by the Social Interaction Deviance Composite (SIDC), which was formed by subtracting scores on pragmatic/social scales from those on the structural language scales. This showed a progressive increase in abnormality going from the SLI group through the PLI and HFA groups, with the Asperger syndrome group obtaining the lowest scores. Nevertheless, there were no sharp boundaries between the groups, but rather a gradual progression.

Australian Sample

Normative data were also collected for 115 Australian schoolchildren aged 6, 9, or 12 years from the Perth Metropolitan Region. In general, scale means for these children fell around one point below the expected mean of 10. It was recommended therefore that different cutoffs should be used for Australian children.

CCC-2, US Edition

US norms were gathered for the CCC-2 US edition on a sample of 950 children aged 4–16 years. This sample was well matched to US population demographics in terms of race/ethnicity, geographic region, and parental educational level. Norms were developed by a process of inferential norming.

Test-retest reliability was obtained by having a subset of respondents complete the CCC-2 on two occasions within a period of 1–28 days. Values were generally high, above .85, for different age ranges. Internal consistency was somewhat higher than that found for the UK sample. Inter-rater reliability was not assessed.

Validity was assessed by considering scores from children from clinical samples including those with SLI, pragmatic language impairment, and autism spectrum disorder (ASD). The criteria for diagnosing pragmatic language impairment are not provided. As with the UK sample, all three clinical groups showed impairments on all ten subscales. SIDI scores of -11 or less were seen in 6% of children with SLI, none of those with PLI, and 27% of those with ASD.

Data on sensitivity and specificity are presented for different cutoffs on the GCC. In general, as with the UK version, the GCC has good sensitivity and specificity for distinguishing clinical cases from typically developing children, but it is not useful for distinguishing between clinical groups.

Clinical Uses

CCC-2 is a useful screening instrument for communication disorders. The General Communication Composite (GCC) is useful for identifying that a child has communication difficulties and few affected children obtain a GCC above the 10th percentile. The GCC is not, however, useful for distinguishing between different subtypes of disorder.

The SIDC is useful for identifying children who have an uneven communicative profile, with disproportionate impairment in pragmatic aspects of communication relative to structural

language skills. This composite has good reliability and is sensitive to autistic spectrum disorders. It is recommended, however, that it should only be interpreted for a child whose GCC is below the 10th percentile.

The CCC-2 is *not* a diagnostic instrument for autistic spectrum disorder (ASD). It can however be useful in screening for ASD. It is recommended that children who obtain low scores on the GCC, including poor performance on the pragmatic scales, should be referred for full assessment for ASD.

The profile of scores on different subscales is too unreliable to be used diagnostically but can nevertheless provide a useful starting point for a discussion with a caregiver about a child's difficulties.

In research contexts, CCC-2 can be useful for quantifying the extent of communication impairment in different domains. Deficits measured by the CCC-2 have been shown to be highly heritable. The CCC-2 has been shown to be sensitive to the broader autism phenotype in siblings of children with ASD.

CCC-2 has also been used with children with genetic conditions such as Williams syndrome, Down syndrome, and sex chromosome trisomies, where it can be helpful in highlighting different communicative deficits.

Developmental Disabilities – Children's Global
Assessment Scale (DD-CGAS)

Description

The Children's Global Assessment Scale (CGAS) is a clinician-rated instrument that provides a single score for the overall level of behavioral and emotional functioning of a child aged 4–16 years. The CGAS is completed by a clinician based on information acquired from direct examination and/or derived from informants such as parents, educators, or case managers. Raters score the

child's most impaired level of functioning for the period of interest (usually the past month) on a scale ranging on a continuum from 100 (corresponding to excellent functioning in all areas of life) to 1 (representing very poor functioning with need for constant supervision). Anchoring descriptors are provided for each decile of the CGAS. While a score of 100–91 indicates *superior functioning* and 90–81 *good functioning*, 80–71 applies to children with *no more than slight impairment in functioning at home, at school, or with peers*. A score of 70 or below is usually considered the threshold for the presence of definite, although slight, functional impairment. Most children referred for clinical evaluation and treatment have scores of 60 or below.

The CGAS has been further modified to meet the need of scoring global functioning of children with autism age 4 and older. This scale is called the Developmental Disabilities – CGAS (or DD-CGAS). The information used for scoring the DD-CGAS relates to four main domain of functioning: self-care, communication, social behavior, and school/academic performance. In each of these domains, the level of impairment can range from none to extreme. The reference for determining the level of impairment is the level of functioning that would be expected by a typically developing child of the same chronological age. Impairment in the main domains of functioning is then used by the rating clinician to formulate a final overall score of functioning (the DD-CGAS score) on a scale ranging from 100 (corresponding to superior functioning) to 1 (indicating extreme impairment). Also the DD-CGAS provides descriptors for each decile (i.e., 100–91: superior functioning within family, school, and peers; 90–81: adequate functioning in all areas; 80–71: most daily living activities at age level but with slight impairment in at least one; 70–61: most daily living activities at age level but with moderate impairment in at least one domain; 60–51: moderate impairment in functioning in most domains; 50–41: moderate impairment in functioning in most domains and severe impairment in at least one domain; 40–31: severe impairment in functioning in some domains; 30–21: severe impairment in all domains and settings; 20–11: extreme

impairment in at least one domain; 10–1: extreme and pervasive impairment with danger to self or others and need for intensive constant supervision). The time frame for the rating can vary but typically is in the order of several weeks or months.

Historical Background

The CGAS was introduced by Shaffer et al. (1983) and is a modification of the Global Assessment Scale developed by Endicott and colleagues in 1976, which, in turn, was a revision of the Health-Sickness Rating Scale, originally published by Luborsky in 1962. A similar scale is the Global Assessment of Functioning (GAF), which constitutes the axis V of the DSM-IV multi-axial evaluation. The DD-CGAS is a modification by Wagner et al. (2007) of the CGAS specifically to score the global level of functioning of children autism and other pervasive developmental disorders. Both the CGAS and DD-CGAS have been translated in languages other than English and are used internationally.

Psychometric Data

When used by raters trained in the clinical evaluation of children with mental illness, the CGAS was shown to have excellent inter-rater reliability (e.g., intraclass correlation coefficient around 0.84), good test-retest stability, and acceptable discriminant and concurrent validity. The CGAS can detect treatment effects. For example, it was able to discriminate between active antidepressant treatment and placebo in adolescent depression. The DD-CGAS too was found to have very good inter-rater and test-retest reliability when used by clinicians who were experts in autism and other pervasive developmental disorders and who had been trained in its use. DD-CGAS scores showed moderate correlation with indices of adaptive behavior, intellectual functioning, and severity of psychopathology. Preliminary data obtained before and after 6 months of treatment indicate a moderate correlation between changes in the DD-CGAS scores and changes on the Aberrant

Behavior Checklist and the Clinical Global Impressions-Improvement scores.

Clinical Uses

The CGAS is a clinically useful instrument that provides an overall score of the level of functioning of a child. The DD-CGAS is specifically useful for rating functioning in the context of autism or other pervasive developmental disorder and is a relatively simple way of indicating the observed global functioning relative to the expected functioning based on normal development. The DD-CGAS allows direct comparisons to be made between functioning of children with autism and functioning of children with other mental disorders such as schizophrenia, depression, or anxiety.

Description

The Children’s Psychiatric Rating Scale (CPRS) is a multidimensional rating scale of childhood psychopathology.

The CPRS is not diagnostic but rather a broad-ranging rating scale of symptoms and behaviors which may contribute to diagnosis. In addition, the scoring system enables the rating of *severity* of symptoms and presentation. Since the scale measures the presence or absence of symptoms over a particular period of time, it has been a useful instrument of treatment efficacy and has regularly been the instrument of choice employed in clinical trials.

Owing to the established subscale structure, an abbreviated form, comprised of 14 questions relevant to the autism spectrum, has been employed in studies evaluating treatment efficacy in autistic children. However, more recently the European Medicines Agency (EMA 2017), *Guideline on the clinical development of medicinal products for the treatment of Autism Spectrum Disorder (ASD)*, has suggested the use of the Childhood Autism Rating Scale (CARS) for baseline assessment and outcome measures in clinical trials.

It has also demonstrated value in evaluating psychopathology in autism, clarifying major behavioral dimensions and identifying distinct subtypes (Overall and Campbell 1988; Overall and Pfefferbaum 1982; Pfefferbaum and Overall 1983).

The CPRS is a clinician-rated scale, based on (1) behaviors observed during clinical interview and (2) the child’s reporting of symptoms. The autism-specific scale is based on observation only.

In the *Diagnostic and Statistical Manual*, third edition (DSM-III, American Psychiatric Association [APA] 1980), a diagnosis of infantile autism is made when four behavioral characteristics are

Children’s Psychiatric Rating Scale, Table 1 Items with respective numbers on CPRS (Overall and Campbell 1988)

Withdrawal (8)	Loud voice (25)
Rhythmic motions (28)	Negative and uncooperative (10)
Abnormal object relationships (7)	Hypoactivity (5)
Unspontaneous relationship to examiner (16)	Fidgetiness (3)
Underproductive speech (2)	Hyperactivity (4)
Angry affect (11)	Other speech deviance (27)
Lability of affect (20)	Low voice (24)

present: (1) *pervasive lack of responsiveness to other people*, (2) *gross deficits in language development*, and (3) *bizarre responses to the environment*. These behaviors can be rated, whereas characteristic (4) *speech deviance*, such as echolalia and pronominal reversal, may be more difficult to evaluate in individuals with little speech. These behaviors are deemed well represented by the 14 items on the autism scale of the CPRS (Table 1).

Historical Background

The CPRS was originally developed by the Psychopharmacology Research Branch of the NIMH as a general-purpose instrument (1976). It featured in the ECDEU Assessment Manual for Psychopharmacology Revised (Guy 1976) among other pediatric scales integral to clinical drug evaluation programs. At this stage, the CPRS was regarded as *experimental*, and no standardization data were available.

The instrument was designed to be employed within a semi-structured interview format to be completed by clinicians and generally used alongside parent- and teacher-completed measures. The rating system facilitated assessment at various stages of a clinical trial, generally prior to the commencement of treatment, during the middle and at the end of treatment. It was designed for use with children up to the age of 15 years.

The first 28 items were rated on direct observation of behaviors at interview, while the latter 34 were rated on the basis of the child's verbal reporting of symptom presence at the time of the interview or during the preceding 7 days. Ratings on a Likert scale were possible from *not answered*, *not present*, *very mild*, *mild*, *moderate*, *moderately severe*, and *severe to extremely severe*. The seven-point scale was effectively derived from the Adult Brief Psychiatric Rating Scale (Overall and Gorham 1962).

The scoring was further developed by Fish (1985). The rating scale comprised of two sections (the original 63 items): in Section A, the clinician rated both the observed behavior at interview and the child's reporting of symptoms or behaviors. Section B represented the clinician's overall view based on the integration of a range of data available, including maternal reports and school records. Hence, additional areas were rated by clinicians with respect to clusters of behavior such as withdrawal, aggressive behavior, hyperactive behavior, inadequate or immature behavior, and organic impairment.

Ratings were made on the degree of abnormality from 0 to 9: *none*, *present but not significant*, *significant but mild*, *moderate*, *moderately severe*, *severe*, *very severe and may be paralyzing*, *item not relevant to child*, and *not known or not ascertained*.

The measure has been valuable owing to the breadth of the range of symptoms and behavioral manifestations assessed while not being limited to the DSM diagnostic criteria, since the scale was originally designed prior to the publication of the DSM-III.

Overall and Campbell (1988) proposed an abbreviated version of the CPRS to evaluate psychopathology in autistic children. They evaluated a subtest of the CPRS, comprising of 14 questions relevant to the diagnosis of autism. Fourteen of the 28 questions of the CPRS are included. Since these are based on *observed* behaviors and symptoms, the subtest is useful for those autistic children who have little or no communicative language and who are severely disturbed or severely developmentally delayed.

Psychometric Data

No normative data existed for the CPRS in its original form (Guy 1976).

Factor-analytic studies have subsequently supported a 6-syndrome subscale structure, hence establishing the internal validity of the CPRS (Overall and Pfefferbaum 1982; Pfefferbaum and Overall 1983).

Evaluation of the diagnostic factor structure of the CPRS (Overall and Pfefferbaum 1982; Pfefferbaum and Overall 1983) confirmed the scale's usefulness in evaluating psychopathology and measuring treatment response in different clinical groups. Seven core factors were identified, namely, *behavioral problems*, *depression*, *thought disturbance*, *psychomotor excitation*, *psychomotor retardation*, *nervous/tension*, and *organicity*. Furthermore, cluster analysis revealed six distinct clusters of symptoms and features, thus enabling the grouping together of those DSM-III diagnoses which tend to have core features and symptom profiles in common. Treatment evaluation could thus be focused on the particular dimensions of symptom presentation.

Studies have served to demonstrate both predictive and construct validity in testing diagnostic classifications. However, like other autism rating scales, the CPRS was developed prior to the revision of autism diagnostic classification (APA 2013; Thabtah and Peebles 2019). To date no data are available regarding how well the autism subscale maps onto the two DSM-5 domains of ASD.

Clinical Uses

The CPRS is a general-purpose instrument for assessment of a broad range of childhood psychopathology.

While the measure is used in its complete form, i.e., a 63-item rating scale, autism-specific research has focused on a subset of 14 items relevant to the condition. The first 28 items on the CPRS are deemed valuable since they are items which are rated on the basis of clinical observation of behavior at interview. Hence, they do not rely on a particular level of language development.

Fourteen of these 28 items have been deemed relevant for the assessment and classification of symptoms and features observed in autistic children (Overall and Campbell 1988). The behaviors included in this subset are well matched with the behavioral criteria for infantile autism first described in the DSM-III (APA 1980), including deficits in language development, odd responses to the environment, and lack of responsiveness to other people.

Overall and Campbell (1988) conducted factor analysis of the subset of the CPRS and noted four core aspects which differentiated autistic children, namely, autism, anger/uncooperativeness, hyperactivity, and speech deviance. In other words, scores on the scale differentiated subgroups. However, these did not necessarily differentiate autistic children from children with other psychiatric conditions.

The 14-item CPRS continued to be employed as the measure of choice in clinical trials (Desousa 2010). It is generally completed by the clinician (s) following videotaped observations of autistic children. This is in conjunction with parental ratings of behavior and symptoms, e.g., Aberrant Behavior Checklist (ABC) and the Conners' Parent Rating Scale – Revised (CPRS-R), as well as other clinician ratings such as the Clinical Global Impression Scale (CGI). The rating scale has demonstrated value in open-label and controlled psychopharmacological trials. Improvement of 25% or more on identified symptoms compared with baseline ratings suggests child is a responder to the medication.

Studies have evaluated tolerability, long-term effects, and efficacy of specific psychotropic medication in autistic disorder as well as comparisons of different medication within this group. Studies of specific psychiatric features associated with autism spectrum disorders and effects of psychopharmacology have employed the CPRS-14 (Gagliano et al. 2004; Desousa 2010). More recent clinical trials (Lemonnier et al. 2017) have followed the EMA guidelines (2017) for evaluating efficacy and impact of treatment, employing measures such as the Childhood Autism Rating Scale (CARS), Social Responsiveness Scale (SRS), and the Clinical Global Impressions (CGI).

Children's Unit for Treatment and Evaluation (State University of New York at Binghamton)

Raymond G. Romanczyk and Jennifer Gillis Mattson
Institute for Child Development, Department of Psychology, Binghamton University,
Binghamton, NY, USA

Definition

The Institute for Child Development (ICD) at the State University of New York at Binghamton

promotes the welfare of children who are challenged by developmental, learning, and emotional disorders. The Institute serves as the focus for service, research, undergraduate, and graduate training programs and the dissemination of basic and applied research. The Institute supports specific units that provide treatment and educational services for children within an evidence-based model. The *Children's Unit for Treatment and Evaluation* provides services for children with autism spectrum disorders and their families in the context of Early Intervention, Preschool, and School Age programs as well as additional complementary programs, such as its Diagnostic Evaluation Clinic.

Historical Background

The ICD was founded by Dr. Raymond G. Romanczyk, a faculty member and clinical psychologist, in 1974, located on the State University of New York (SUNY) at Binghamton campus. An ICD program, the Children's Unit for Treatment and Evaluation, was established in 1975 in cooperation with a small group of parents who wished to receive evidence based and intensive services for their children. Given the efficacy of the program, parents worked with local and state legislators to provide the Unit an appropriate connection to the region's continuum of services. Special status was granted in 1977 through an act of the New York State Legislature (Senate Bill 5911-A) which allows the Unit to exist with a dual status as a fully certified New York State Education Department private school and at the same time organizationally part of SUNY at Binghamton. The bill permits school districts, counties, and other state agencies to contract directly with the Unit for services. This also allows the Unit to function as a separate entity at the University level, rather than as the more typical "lab school" or time-limited grant-funded project. The Unit was the first in New York to provide full-day intensive evidence-based services for children in the early intervention and preschool age range.

At its start, the Unit served just six children from the immediate area. The catchment area has

grown quite large and now includes the New York State counties of Broome, Tioga, Cortland, Tompkins, Chenango, and Onondaga and the Pennsylvania counties of Bradford, Susquehanna, and Sullivan, representing locations across urban, suburban, and rural areas. Currently approximately 65 children commute daily to the program from within an approximately 90 mile radius.

The ICD has had multiple locations on the campus since 1973. In 2001 the Institute was moved to a spacious specially constructed building for the sole use of the ICD. It is located next to the campus preschool services building, permitting ease of cooperative programs for peer-based activities. In 2013 Dr. Jennifer M. Gillis, faculty member, clinical psychologist, and licensed behavior analyst, became the co-director.

Rationale or Underlying Theory

An autism spectrum disorder affects not only the individual but also the family, the community, and the broader society as well. As a group, the impact on families is greater and more complex than many other disorders. This requires an intensity, quality, and precision of educational and clinical services that are not only directed at the individual with an autism spectrum disorder but also the family. Comprehensive service delivery cannot be impeded by bias, inappropriate, and antiquated organizational structures, low expectation, or by compartmentalization of services.

The guiding principle of the Institute for Child Development is that providing a caring, warm, supportive, enriched environment that respects the dignity of individuals and celebrates their unique qualities and potential is the *minimum* starting point for educational and clinical services. This principle is paired with a comprehensive commitment to evidence-based services drawing upon well-conducted, methodologically sound, empirical research. Thus, educational and clinical research is utilized on a continuing basis, and the ICD provides mechanisms and opportunities for all program staff to acquire and use research information on a timely basis, which includes weekly in-service training, journal

club, visiting speakers, and consultants, as well as attendance at professional conferences. Another priority is that there must be extensive, precise, quantitative, and frequent child assessment that permits the daily implementation of an objective feedback loop for decision-making regarding appropriate goals, procedures, and progress.

Given the emphasis on evidence-based approaches to intervention, current practice is based upon research in behavioral approaches (applied behavior analysis and cognitive behavioral therapy), developmental models (Early Start Denver Model), nomothetic and ideographic assessment (such as functional behavior assessment), family systems, curriculum selection, basic attention and learning processes, social development, and comorbid disorders. The program employs a comprehensive model, but it is not based on a specific single "model" or particular "approach," but rather is dynamically based on contemporary, methodologically sound, peer-reviewed research that has been replicated.

Goals and Objectives

The program provides full-day, 12-month services with emphasis on individual evaluation of each child's assets and deficits, past history of services and response, current functioning, the specific parameters of the child's learning pattern, and an analysis of maintaining factors of current behavior patterns using functional behavior analysis. The goal of the program is to remediate skill deficits that prevent children from participating at their potential in the continuum of education services in their community and to provide families with training and support for their own needs. Emphasis is placed on acquisition of communication skills, social interaction skills, self-regulation skills, and reduction of stereotyped behavior and restricted interests. The average length of enrollment is 2.5 years as the emphasis is upon rapid reintegration into services in the child's local community. Thus the ICD is not a long-term alternate educational placement but rather an intensive, focused, short-term intervention program.

Prioritized goals within a comprehensive program produce rapid transition to services in the child's community.

- Ongoing progress monitoring (measurement for decision-making feedback loop)
- Family/caregiver involvement (to address both child and self needs)

Treatment Participants

Children between the age of 1 and 11 are eligible to attend the program. Referrals come from physicians, county health departments, and school districts via the NY system of Early Intervention Officials, the Committee on Preschool Special Education, and the Committee on Special Education. Because the catchment area is so expansive, admission criteria is based on a relative analysis of the child and family's needs in the context of the resources of the continuum of services in the community of residence. The majority of children are diagnosed with autism spectrum disorder and have a history of poor response to intervention prior to admission. Parent willingness and ability to participate in the child's program and attend family service groups are highly variable upon admission and are not a selection criteria. It is explicit that admission is not based on parent's willingness to participate in ongoing research projects, as such a requirement would be deemed coercive.

Treatment Procedures

Comprehensive intervention requires that at minimum primary focus is placed on the core ASD areas of social communication and social interaction and restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. Further, salient comorbid disorders must be assessed and addressed, e.g., anxiety disorders.

Next, a continuum model for comprehensive intervention is used (Romanczyk and Gillis 2010) that includes several critical procedural components:

- Assessment (nomothetic and ideographic)
- Curriculum planning (goal selection, prioritization, and sequencing)
- Intervention methodology (evidence based)

It is these components that are used to achieve acquisition of skills and address behavior problems with emphasis on generalization of skill repertoires in normative settings. A comprehensive developmentally organized curriculum, the IGS Curriculum (Romanczyk et al. 2000), is used to guide and structure assessments and precise goal specification. Utilization of a curriculum that provides a developmentally sequenced compendium of goals permits identification of skills associated with the child's strengths and weaknesses, guides further assessment of the limits of the child's skills and performance, and permits meaningful discussion of goal selection and priorities with parents as it helps in supplementing their knowledge of child development. A comprehensive curriculum that is developmentally sequenced such as the IGS ensures that assessment is directly linked to functional instructional goals. Appropriate staff are also certified Early Start Denver Model (ESDM) therapists and also trained in the use of the Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP).

Settings for instruction, instructional procedures, and specific goals present a complex mix of variables. Their interaction must be addressed to allow optimal configuration from the perspective of each factor. As an example, if emphasis is currently upon transition between two instructional settings, then goals and procedures need to be adjusted to be appropriate within that context.

Likewise, if focus is upon acquisition of a specific goal set, then settings and procedures are adjusted to maximize speed and strength of learning. This is a dynamic process, allowing adjustment to changing child and family characteristics, as well as resource factors, while developing more and more sophisticated child repertoires. No one variable has primacy, with emphasis placed on a coherent comprehensive program.

Social development is a priority, and the program is designed to improve social skills and

social problem-solving. Activities are constructed for individual strengths and deficits. Activities and projects focus on skill strengthening via use of modeling, rehearsal, role-playing, cognitive behavior therapy, and anxiety reduction approaches.

A second component is the strong cooperation with the University Campus Preschool which is in a building physically adjacent to the Institute. Children from the Institute attend the preschool on a part-time basis as a transition step as part of preparation for returning to program's in their school district of residence. Staff of the Institute accompany the children and serve as guides for the preschool staff to integrate the children into typical activities.

A third component is the "Buddy Group," an after school therapeutic social skills program. The program focus is on increasing the quality of social interactions through participating in a variety of on-site and community activities with typical peers. Peer volunteers are area middle-school children who function as "buddies" by relating to children with ASD as they would any other friend. This provides realistic feedback and experiences as would be encountered in typical casual social settings and allows for more success in meeting complex social expectations. Teaching objectives focus on age appropriate activities, learning social expectations, and responding appropriately to the inherently variable consequences of social interaction.

A fourth component is an extension that we term "SLC Saturday." The Institute has a very large specially constructed playground with a state-of-the-art injury prevention focus and various types of play areas that permit quiet self-play as well as areas that support and encourage social interactive play. It can accommodate more than 150 individuals comfortably and safely. It is used on a daily basis for children enrolled at the Institute and is the focus for social development. SLC is the acronym for Social Learning Center. This facility is opened on Saturdays for families of the Institute as well as the community, permitting a safe and choreographed setting for interaction between children with ASD and typically developing children.

Family Focus

A separate but highly intertwined program emphasizes individualization of services. Family involvement is strongly encouraged and supported. Because a child with an ASD affects the whole family, this greatly influences the family services provided. In addition to instruction in specific procedures and skills so that families can conduct teaching programs at home, measure progress on specific skills, and objectively evaluate their child's performance, the staff individually tailor parent services to the needs and values of each family. Families can choose from a variety of ongoing services that include:

- Didactic instruction to implement intensive language and social/emotional programs at home.
- Homework programs with parent with training so that they can conduct more traditional "homework" pre-academic/academic, leisure, and self-help activities at home.
- Periodically themes are identified for a "family-friendly" personal goal. Activities focus on workshops for parents, individual support meetings, and parents participating in school activities. Staff then increase emphasis on addressing these goals at school and paralleling with home programs to maximize generalization and thus family success.

An important additional program component is parent wellness. Wellness sessions are devoted to assisting caregivers in appropriately addressing individual family member needs with particular emphasis on stress management. Components of the program include recognizing and quantifying stress, changing stress responding through relaxation training, diaphragmatic breathing, progressive muscle relaxation, guided imagery, yoga, time management, and cognitive restructuring approaches.

Technological Innovation

There is significant use of technology, particularly computer technology, with individuals with ASD. However, great caution must be exercised in

applying a technological approach to a problem that is at its core a social interaction disorder.

The ICD has been applying technology to the provision of services since the 1970s and has been acknowledged as a pioneer in this area. Staff are provided with sophisticated organizational systems and technology to address the program priorities. Appropriate utilization, however, requires precise matching of need with solution. A major focus has been to provide staff with useful tools that match their needs and abilities for application in complex and changing circumstances.

From an administrative perspective, the problem of efficiently collecting, organizing, interpreting, and monitoring the voluminous information need to achieve comprehensive program goals represents a continuing challenge. We utilize a series of computer databases to organize each student's educational goal plan, specific habilitative goals, daily and monthly progress on each goal, graphs of progress, history of educational goals, and evaluation of goals. Our curriculum database is connected to above the databases, which allows the selected goals from the IGS to be imported into a student's goal plans' database. From this database, printed reports are generated as well as large screen video projection for staff meetings for review of individual children's goals and progress. The use of extensive computer-based analytic tools for staff, high-efficiency database software for goal selection and monitoring, and extensive use of handheld computing devices with custom-developed software for numerous specialized activities is essential for efficient day-to-day operation within a normative, constrained program budget. The twin goals of the technology program are to improve accuracy and speed of data-based decision-making while simultaneously reducing staff "paperwork" tedium which in turn allows more time to focus on child and family needs.

Efficacy Information

The ICD is one of the ten model programs cited in the Educating Children with Autism report of the

National Research Council (2001) that was commissioned by the US Department of Education. The Committee on Educational Interventions for Children with Autism utilized specific selection criteria in their search for model programs, based upon published reports and frequency of citation. They identified ten programs based upon their criteria, to illustrate "state-of-the-art" model approaches, which included the Children's Unit for Treatment and Evaluation.

Because the ICD is an evidence-based program as described above, there is a large body of research studies that are constantly increasing. Some relevant summaries of this research body include:

Outcome Measurement

For an applied educational/clinical setting, it is not possible to determine which specific factor or combination of factors are the most influential in outcome. That requires controlled research with standardized procedures, specifies duration, and appropriate control groups. The explicit goal of the ICD is to quickly transition children from diverse families and communities to their home school districts and to enable them to participate in the services in their community. The specifics of this transition are unique for each child and do not represent the achievement of an absolute level of functioning. The duration of participation is variable within the average of 2.5 years.

Within these non-research parameters, approximately 50% transition to typical educational settings, 25% to “inclusion opportunity” classrooms, and 25% to “self-contained” classrooms. Importantly, recall that our exit criteria are specific to child, family, and school district goals and do not reflect “absolute” criteria. Thus a given family and school district may have typical placement as their goal, while another family and district have the goal of as quickly as possible having the child participate in their continuum of services (this is often the case for children who must travel substantial distances each day to the program).

The formal research that is conducted at the ICD focuses primarily upon measurement/assessment, process, and focused intervention outcomes. Some recent examples are:

Qualifications of Treatment Providers

All professional staff hold appropriate licenses and certification for their respective professions. Additionally, 30% of the professional staff are also Board Certified Behavior Analysts. The staff represent the following professions:

- Clinical Psychology
- Special Education
- Behavior Analysis
- Nursing
- Speech Pathology

Occupational Therapy School Psychology Adaptive Physical Education

In addition to professional staff, there are full-time staff in teacher aide, administrative, and technical staff positions.

The ICD also has extensive educational programs. At the undergraduate level, there is an intensive four-course sequence, three of which have practicum components that complement the requirements of the major in psychology. The course sequence has been evaluated by the Behavior Analyst Certification Board as a Verified Course Sequence. Selected graduate students in the doctoral clinical psychology program, in addition to the program requirements, participate for 4 years as staff members at the ICD under the supervision of senior staff. Training is also provided for select postdoctoral fellows as well as medical students.

³Marcus Autism Center, Emory University, Atlanta, GA, USA

⁴Child and Adolescent Psychologist, Private Practice, Santiago, Chile

Historical Background

The first initiatives providing help for individuals with Autism Spectrum Disorder (ASD) in Chile were, as it is usually the case, spearheaded by parents of autistic children, whose initiatives founded many organizations that provide services to this day. The largest national support organization, ASPAUT, or the Chilean Association of Parents and Friends of Autistics, was founded in 1983 in Santiago. Today, the nonprofit organization has branches in five of Chile's 15 regions, with 1,400 members nationwide. Its services include four schools, five family support groups, and one vocational training center. Though each location is associated by name, each operates as an independent entity.

Legal Issues, Mandates for Services

The department of special education of the Ministry of Education indicates that in 2009, 589 students diagnosed with autism were receiving educational services under the law *Decreto Supremo N° 815/1990* which guarantees special education services to individuals with Autism, severe Dysphasia, and/ or Psychosis.

Overview of Current Treatments and Centers

Multiple research findings indicate that early identification and diagnosis of ASD can improve

opportunities for children to benefit from interventions and lessen the burden on parents (Zwaigenbaum et al. 2013). The key to early diagnosis is access to competent and effective diagnostic and treatment services. In Chile, health care can be accessed through both the public and private systems.

Public Health Care

Though Chile does provide services through a public health-care system, hospitals are not equipped to attend to individuals with an ASD, even though several laws regarding the disability exist. Parents who do receive medical services through the public health care system have great difficulties in making appointments with specialists such as neurologists or psychiatrists, and if they are successful, encounter very long waiting periods, which, in turn, inhibits the possibility of an early diagnosis and thus early intervention. Even after a diagnosis is made, it is practically impossible to access support and treatment from a multidisciplinary team, on a continuous basis, through the public health system. Furthermore, the government does not guaranty coverage of any treatment related to ASD. In addition to the general public health-care system, there is also a list of 69 illnesses or conditions for which the government guarantees free treatment. ASD is not included in this list (Ministerio de Salud 2010).

Private Health Care

In Chile, there is also a private health-care system. Unfortunately, even after paying high premiums for private health insurance, the coverage for the payment of specialist services is very limited, sometimes as low as one or two sessions a year, or the coverage of a very small percentage of the session's actual cost. Typically, professionals in the private sector work independently, not in an integrated center or fashion, leaving parents with no choice but to shuttle their child to different specialists, who do not communicate with one another, for different treatments. High costs and inadequate service provision through the private health system places great financial, emotional, and practical strains on families. Very few private

centers for developmental disabilities have a multidisciplinary staff that works in an integrated fashion.

Obstacles to Quality Service Provision

Autism spectrum disorders place huge strains on families. These can be quantified in terms of financial investment, time lost from work, and time not spent with other family members. Other strains can only be described, such as levels of stress experienced, impacts on relationships, the mental health status of other family members, and lost personal time of professional careers. In fact, many families suffer from severe dysfunctional relationships leading to parental separation, anxious distress, and psychological problems in siblings.

Financial Burden

One of the most common obstacles to receiving treatment services is that of lack of or restriction of financial means. All but one family interviewed for this study stated that their level of financial resources negatively affected the quantity as well as the quality of the treatment their child received. Only one family, one of substantial financial means, stated that the quantity of treatment that their son received was adequate.

Apart from the financial burden placed on families by both the public and private health-care sectors, lack of professionals trained the area of Autism in Chile creates further obstacles to correct diagnosis and early intervention. All children in this study were seen by various professionals including psychologists, neurologists, and child psychiatrists, and received varying diagnoses. Many of these professionals have varying degrees of training and experience in ASD and also use a variety of classifications, nomenclature, and treatment approaches.

Diagnosis

Of four families interviewed and four further cases reviewed, only one child in this study received a diagnosis of Pervasive Developmental Disorder (PDD) as a first diagnosis. Two children received diagnosis of Dysphasia, three of a general language disorder, one of a nonspecific

behavioral disorder, and one of Schizoid Personality Disorder, respectively, all previous to their diagnosis of ASD. Typically, the first professionals to recommend an evaluation were speech therapists, either within the educational setting or in private practice. At least four children received their diagnosis of an ASD from a neurologist. There is a cultural bias against consulting with psychiatrists, leading to underconsultation with these professionals until later in the process. Deficits in professional development and training in the area of ASD can be seen through significant delay in establishing an early and appropriate diagnosis and poor management in several of these cases.

Cultural Aspects

Obstacles to quality service provision and care can also be found in specific cultural aspects. One unexpected cultural aspect that presented itself in two interviews with center directors interviewed in this study was that of, what could be referred to, as *cultural protectiveness*. One director commented that professionals in Chile are often very guarded about their knowledge of a specific area and do not want to share this or work collaboratively with others for fear of competition in the area. One director also stated that there is a lack of trained professionals in the area of ASD in Chile, notwithstanding, she would not employ any foreign professional, regardless of their training or experience, as “they would not know the reality of Chile.” These opinions were spontaneously expressed without prompting through the interviewer’s questioning. Clinical work, following the psychoanalytic method, tends to be considered “in-doors” and “confidential,” which leads to the lack of communication and poor team work in many instances.

Centralization

Centralization of specialists and services that are available, to Santiago, the capital city of Chile and surrounding areas, poses further obstacles to diagnostic, treatment, and support options for families outside the greater metropolitan Santiago area. The limitation of access to services can be seen in the distribution of autism-specific education

and treatment services throughout the country. Except for Valparaiso and Concepcion, the rest of the country lacks trained professionals.

Service Provision

The following diagram presents the governmental bodies responsible for service provision for individuals with disabilities, accessible in the public sector (Fig. 1).

It is important to note that no governmental body provides direct funding or services for the individuals with ASD. This includes the National Service for Disability.

If organizations would like to receive support through this office, they must apply for funding based on a project proposal. Funding is not guaranteed and is very difficult to obtain.

Educational Services

According to the Ministry of Education, in 2013, there are 15 publicly funded schools throughout the country that offer educational services specifically to children with ASD. These schools are located in seven of Chile’s 15 geographical regions, with five located in the Metropolitan Region of Santiago and four in the neighboring region of Valparaiso. Thirteen of these schools are managed by nonprofit organizations that receive funding from the Ministry of Education, on a monthly basis, based on the number of children that attend. Two of these schools receive funding through their municipalities. There is no school directly run by a government body. There are no privately funded schools that specifically support children with autism.

Integration Programs

Chilean law guarantees access to, and integration in, the educational system for all individuals with special education needs. The Ministry of Education satisfies this requirement by giving public schools the opportunity to have an “integration program” by way of contracting a multidisciplinary professional team through government funding.

Public, no profit, or municipality schools receive funding based on what type of disabilities their special needs students have, and how many

Chile and Autism,

Fig. 1 This diagram presents the governmental bodies responsible for service provision for individuals with disabilities in the public sector. Gobierno de Chile (2013)

of them attend. Students with special needs are either considered to have transitory special needs or permanent special needs. Transitory special needs include borderline cognitive disabilities, Attention Deficit Disorders, and specific language and learning disorders. Permanent special needs include cognitive disabilities, physical disabilities, auditory or visual disabilities, and Autism.

According to the Ministry of Education, there are 4,500 public schools in Chile receiving funding for integration programs in 2013. Schools that accept students with special needs are required to redefine their educational projects, adapt their curricula, and implement support systems based on the needs of their students. They must also evaluate and monitor these needs over time as well as train teachers and staff. Students receive a minimum of 10 h of special support per week.

However, in order to receive funding for a multidisciplinary professional team, a school must have at least five transitory special needs students or two permanent special needs students in the first grade level who wish to attend. This begs the question of what kind of support students with special needs in small communities or in

rural areas receive, when pure lack of population limits their access to funding under the governmental initiative.

Some private schools also offer integration programs. The cost of professionals such as educational psychologists is covered by the tuition of all students. However, the parents of a student with special needs must personally cover the costs of any extra support their child might need including special education teachers, classrooms aids, tutors, or “shadows.” Private schools with integration programs often have very strenuous limits on the number of special education students they accept. This may be a limit of five special needs students for a school population of over 1,000 students. Being private institutions, they are under no obligation to accept any student with special needs, if they so choose.

Organizations for ASD

There are currently seven organizations in Chile that provide services specifically to individuals with ASD. These services include schooling options, diagnosis and therapeutic services, and psychoeducation and support for parents and families.

Five of these organizations are located in Santiago, one in Vina del Mar, about 120 km from the capital and one is an internet-based virtual support and advocacy group. Two of these organizations provide support and education through informative websites and chat rooms. One of these specifically supports individuals with Asperger’s Syndrome and their families and only one, ASPAUT, has centers located in various regions of Chile.

Figure 2 below illustrates important aspects of services provided by these organizations including funding, diagnostic tools used, intervention methods utilized, and training of their directors:

Four directors interviewed for this study, three special education teachers and one psychologist, stated that they had not received any education or special training about autism in their University courses. All of them subsequently sought specific education such as training in ABA and PECS either outside of Chile or through visiting international professionals, such as Theo Peeters.

There are also at least two private rehabilitation centers in Santiago that provide diagnostic and therapeutic services to individuals with ASD. Both

provide services through multidisciplinary teams. One center utilizes standardized clinical diagnostic tools while another utilizes its own clinical method. One center provides treatment options based on a mix of ABA, Floortime and TEACCH, while the second provides group therapy, Floortime, and occupational therapy with sensory integration, speech therapy, medication treatment and “Bio- Diets” in connection with two referring pediatricians.

Overview of Research Directions

Children and adolescents under the age of 15 make up 22 % of Chile’s population (WHO 2010).

As stated by the Chilean Ministry of Health, there have been no epidemiological prevalence studies of Autism or ASD conducted in Chile and there is no registry of diagnosed cases. However, based on calculations using the international estimate of prevalence of nine children with autism in 1,000 and 240,569 registered births in Chile in 2007, the Ministry (2011) estimates that

Chile and Autism, Fig. 2 This graph indicates the number centers of service provision in Chile who satisfy each descriptor (*Include Psychologists, Speech- Therapists, Physiotherapists, Special Ed. Teachers, and referring Psychiatrists. **Include ADI-R, M-CHAT, IDEA, Vineland) (Note: *Permissions:* The information presented in the

diagram has been cited. The diagram itself is a creation of the author Sonja Ziegler. The information presented resides in the public domain. The illustration (bar graph) is a visual presentation of data collected during research. It was created by author Sonja Ziegler)

the approximate number of children with a diagnosis of an Autism spectrum disorder would be 2,156. According to the National Inquiry of Disability in 2004, 15,000 individuals presented with severe language disorders, or one in 1,000, using the population registry of 15,000,000 inhabitants of the 2002 census. This estimation does not differentiate between various possible diagnoses.

Though Autism is a global issue, affecting individuals of all ethnicities, clinical and research publications in the field are heavily focused in developed countries, with the United States, Canada, and the United Kingdom being leading publishers. Comparatively, publications in the area of ASD in Latin America are rare, and almost non-existent in Chile (OARC 2012). Thusly, little is known about the magnitude of the problem.

In a review of the Chilean national publication database, only six articles related to ASD have been published in the last 27 years. Three of these articles are clinical descriptions, two are case studies and one is a literature review.

Clinical Description

Though autism is defined as a developmental disorder that manifests itself in the first three years of childhood, its symptoms continue throughout an individual's lifespan. Irrázaval et al. (2005) presented a clinical description of the disorder based on diagnostic guidelines of the DSM- IV- TR, prevalence, and psychopathology from infancy through adolescence. Adult Autism was discussed through a case study of a 23-year old man brought to psychiatric evaluation by his mother. Neurobiological aspects of autism and the use of psychotropic medications in individuals with autism were also discussed. Quejada (2008) presented a clinical description of the disorder through genetic etiology, diagnosis, differential diagnosis, and prognosis. Flora de Barra also presented a clinical description of ASD based on the ICD- 10, genetic etiology, and differential diagnoses (1995).

Genetics

Individuals with autism usually present with cognitive difficulties. About 16–40 % of those with cognitive problems present with profound deficits. Flora de la Barra et al. (1986) reviewed a

case study of two identical twin girls with autism and profound cognitive deficits, who presented with an apparently balanced chromosomal translocation.

Treatment

After a definitive diagnosis of autism, it is important to evaluate how a child's development can be supported and their symptoms alleviated. Morales et al. (1995) presented a case study in which a 9 year-old institutionalized boy with autism improved in the areas of language, social interaction, and stereotypical behavior after several months of systems-focused family therapy with his father, mother, and older brother.

Review of Aetiologies and Alternative Treatments

A growing number of parents are adopting alternative or complementary treatments such as diet restrictions, chelation therapy for heavy metals, the use of hyperbaric oxygen chambers, elimination diets, as well as refusing to vaccinate their children due to a variety of beliefs regarding ASD aetiological hypothesis. Higuerra (2010) presented a critical literature review of studies related to these treatments, highlighting their methodological inadequacies and inconclusiveness. This article is very important to furthering professional development in Latin America. From a cultural perspective, the fact that it is written in Spanish, by a Chilean, adds a great deal of validity and weight to its contents.

Though research in the area of autism in Chile is scarce, the articles that do exist seem to represent the level of knowledge of the field among some professionals, as well as accounts of clinical work with patients.

It is important to note that there are no articles published in PubMed specifically related to Chile and Autism

Government Publications

The Chilean government has published three informative guides on ASD for teachers and health-care professionals, respectively: two through the Ministry of Education and one through the Ministry of Health.

Ministry of Education

Both guides from Ministry of Education are written specifically for teachers. One focuses on detection, intervention, and teaching methods for solely children in the preschool age group, while the second focuses on all schooling levels, including university.

For the preschool level, the guide begins by describing ASD based on the DSM- IV-TR diagnostic criteria, history of the diagnosis and the three areas of impairment. There is also a presentation of aetiological theories. The guide also presents guidelines for early detection and intervention, as well as suggestions on how to speak to families if a need for a clinical evaluation is suspected. Lastly, the guide presents recommendations for the educational-teaching process. It gives concrete examples for preparing lessons, how to structure the learning environment based on the needs presented through the disorder, how to involve the family in the continual learning process at home and provides examples of activity planning and execution (Ministerio de Educación 2010).

Though the guide can be seen as generally helpful, it does have several and significant deficiencies. One being that some information provided is conflicting and at times simply wrong, such as the description of Asperger's Syndrome as a language disorder. Providing false information to a group of professionals who are not likely to receive any further education or training in the area can have limitless repercussions. The guide also gives the impression that intervention at 5 or 6 years of age can still be considered early, and does not emphasize the need for the earliest intervention possible in order to obtain the best outcome for the child (Ministerio de Educación 2010).

The second educator's guide for all school levels also speaks in length about the history of the disorder, diagnostic criteria, and early alert indicators. It presents examples of the M-CHAT and ASSQ for educators' use. The guide describes the specific early intervention methods of Lovaas and TEACCH. For school-aged children, the guide discusses the need for individual evaluation of each child's needs and gives general tips on

supporting a child through their scholastic development. Subsequently, it describes specific characteristics of children with a diagnosis of Asperger's Syndrome.

Lastly, the guide describes the general abilities and impairments that young adults with Asperger's Syndrome typically present in relation to their entrance into the University setting. It provides suggestions for teachers as well as administrators in how to best teach and provide support for individuals with Asperger's Syndrome (Ministerio de Educación 2010).

It is important to note, that in speaking with the author of the guide, she stated that the guide was commissioned as a demonstration of best practice by the Ministry of Education. However to her knowledge, the guide is not actually in significant use within the school system.

Ministry of Health

The Ministry of Health has also published a guide for the clinical detection and diagnosis of ASD, for health-care professionals. All guidelines follow international standard. Steps of early detection, diagnostic evaluation through multidisciplinary teams, and therapeutic interventions are discussed. A multifaceted evaluation using standardized measures is recommended. Behavioral focused treatment options presented include ABA, PTR, and early intensive behavioral intervention. DIR, Floortime, and sensory integration are also discussed. Augmentative communication systems such as PECS, TEACCH, and TCC are presented, and the roles of various medical professionals in the treatment process are explained.

Though this guide presents a best practice model of detection, diagnosis, and treatment for ASD, its application in practice is virtually impossible in Chile due to the multiple hindering factors discussed previously. Based on statements from the four families interviewed and the four cases reviewed, in relation to their diagnostic processes and experiences, it does not seem that the contents of this guide are being taught to the professionals most likely to be involved in the lives of individuals with ASD and their families.

Social Policy and Training

Autism profoundly affects individuals with the diagnosis, their families, and in turn societies. In reviewing the data collected for this chapter on Autism in Chile, it seems as if the knowledge to improve the lives of individuals with ASD and their families through correct early diagnosis, effective early intervention, and treatment as well as long-term support provision is available. It is the lack of implementation of this knowledge that prohibits thousands of individuals with ASD in Chile from receiving the quality and quantity of services needed to reach their full potential.

Governments have an obligation to provide support to individuals with ASD. In Chile, governmental interest and investment in all areas related to autism would be the first step to improving the outcomes for all autistic individuals. Government bodies must guarantee that all resources, including proper diagnosis, high quality treatment, and education are both financially and physically accessible to all its citizens. This can be achieved through proper government investment. This can also be achieved through the regulation of private health sector and the services offered within the system.

The Ministry of Education must ensure that their educational professionals are trained in all aspects of autism and on how to provide students with ASD with the best education and care possible. This would include training for all professionals currently in the field, as well as incorporating autism education and training into the curricula of all public and private educational institutions.

Governments also have a responsibility in overseeing the education and training of its medical professionals, regardless in which capacity they practice or in which school of medicine they have trained. Professionals practicing in Chile need to be trained in the variety of aspects of ASD, its differential diagnosis and treatment options. Diagnosis and treatment methods must be included in the curricula of all medical schools. This training is vital for primary care professionals, who are typically the first professionals to come in contact with children who present with

worrisome signs and symptoms of developmental delays and distortions. Initiatives for early diagnosis and intervention must be made a national medical priority. Correct early diagnosis and intervention also reduces the financial, emotional, and practical strains and burdens experienced by family members.

Governments through their Ministries of Health and Education must also take an active role in providing services to individuals with ASD. These governmental bodies must define a protocol which would clearly delineate the path of "best care" through "best practice strategies." They must train health, educational professionals, and parents about these strategies and enforce their implementation.

Government interest is also needed to improve research in the area of autism in Chile. Without knowing the prevalence and the status of the disorder in a population, it is difficult to develop effective strategies for prevention, intervention, long-term care, and positive outcomes that reflect the specific needs of the country and culture.

In regards to service provision, it is important that all individuals have access to support and services throughout their lifespan: child, adolescence, and adulthood. This promotes personal development, better outcomes, and alleviates some of the strain experienced by family members responsible for lifetime care. Each child diagnosed with autism today will one day be an adult with autism. There is a great need in Chile for more vocational training and rehabilitation centers throughout the country to accommodate the need of adults with ASD.

Lastly, there is a great need for equalization of accessibility to quality care provision between the public and private sectors.

Autism is a universal severe developmental disorder that is also present in Chile. The development of service provision for individuals with autism has sprung from the determination and self-reliance of parents and family members and in most cases it seems still greatly dependent on their resilience and fortitude. Currently, lack of interest, investment, and regulation by government bodies hinders the development of research and practice in the field, as well as access to

quality medical care, treatment, and support services for many Chileans with ASD and their families.

Acknowledgment The authors of this study acknowledge that during its preparation for publication, the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition. (American Psychiatric Association 2013) was published, and acknowledge that under these new diagnostic guidelines, the definition of Autism and ASD has changed. However, the authors also acknowledge that when changes occur, the utilization of new diagnostic guidelines is a scientific and cultural process for both professionals and patients. Thusly, the authors chose to present the study's data as defined by the Diagnostic and Statistical Manual of Mental Disorders 4th Edition, Text Revision (American Psychiatric Association 2000).

China and Autism

Jared Cohen

Yale Child Study Center, Yale University, New Haven, CT, USA

Historical Background

The history of autism in China is a brief one, as it was not diagnosed there until 1982 (Tao 1987). Since that point, the landscape of research and scholarly work pertaining to the epidemiology

and clinical care of autism and related disorders has been relatively bare. Some of this can be attributed to the fact that dozens of dialects are spoken throughout the mainland, leading to a relative lack of appropriately translated materials relating to the diagnostic and treatment practices of autism (Ming 2013). This has left many doctors, teachers, and a majority of the general public with a lack of awareness and understanding of the disorder.

China has a long history of special education schools, dating back to the early twentieth century and through the times of Mao Zedong (Deng et al. 2001). These institutions have been mostly geared toward those suffering from blindness and deafness, rather than those with intellectual disabilities, however (Yang and Wang 1994). Consequently, programs and schools for those with autism have been much more difficult to come by.

Legal Issues, Mandates for Services

Beginning in 1986, the Chinese Government began enacting a slew of legislation intending to benefit the disabled. The first landmark act was the China Compulsory Education Law, which aimed to require public schools to accept children with special needs (Deng et al. 2001). This was followed in 1990 by the Law of the People's Republic of China on the Protection of Persons with Disabilities, which called for additional protections of Chinese individuals with disabilities under the law (McCabe 2007). Moreover, through its Ninth, Tenth, and Eleventh Five-Year Plans, the Chinese Government continued to outline ways in which to increase support for disabled children as well as improve their enrollment in schools (Ming 2013). Yet, although autism was first diagnosed in 1982, it was not officially included as a disability covered by Chinese law until 2006 (Gu 2007).

Despite these apparent attempts to increase support for those with autism and other disorders, the vague goals outlined in such legislation

have yielded minimal results. Autistic children are still often refused an education from government-run public schools, including special education ones (Huang and Wheeler 2007). Public schools can cost almost half of a Chinese citizen's average annual salary, while private schools often cost two to three times the average amount (Ming 2013). For children that live in rural areas, it can be incredibly difficult to even find a school that offers the proper services (Wang et al. 2011). It is not uncommon for a special education school to admit an autistic child only to later declare that its teachers have an improper background in working with children with such conditions (Rubin 2000).

Due to the shortcomings of China's state-run programs and educational system, many families and autistic individuals seek intervention from private organizations (McCabe 2004). Such treatment is paid for out of pocket by parents or families (Gu 2007; McCabe 2007), which can become an obvious financial burden. The cost of such services in China is an issue for many families.

Overview of Current Treatments and Centers

While Chinese public and private schools have fallen short for most autistic children, a number of nongovernmental organizations have begun to emerge. One of the more notable examples is BARAC: the Beijing Association for the Rehabilitation of Autistic Children (Feinstein 2010). Run completely off of fees and private donations, BARAC offers a hotline for parents of autistic children, publishes newsletters and journals to raise autism awareness, and oversees two schools specifically for autistic children, each with over 100 students (Feinstein 2010). A number of similar centers now exist within China's major cities, though very few exist in China's rural areas and countryside. Many of these organizations have been started by the parents of autistic children who had difficulty finding services or getting an education elsewhere (McCabe 2007).

In terms of the diagnosis of autism within China, many doctors use the *Chinese Classification of Mental Disorders, Third edition* (CCMD-3) (Wu and Zhang 2011). Professionals have argued that changes should be made to improve the accuracy and consistency of diagnoses of autism (Wu and Zhang 2011). Currently, very few internationally recognized clinical diagnostic tests, such as Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observation Schedule (ADOS), are used by doctors (Wu and Zhang 2011).

Overview of Research Directions

Research on autism in China has been very limited, though the volume has been increasing as awareness has increased. Moreover, organizations such as the Autism Consortium China are emerging and beginning to change the landscape of research within the nation (Wu and Zhang 2011). Launched in 2009 by a group of Chinese research scientists and doctors, the Autism Consortium China seeks to spread awareness of autism in Chinese society, help standardize and improve diagnostic procedures, and conduct extensive research on autism within China (Wu and Zhang 2011). While much of the research that has been conducted within China has focused on infantile autism, early intervention, or special education, adults with autism have seemed to be an area that research has neglected.

Overview of Training

Public schools often justify their rejection of autistic children by claiming that their teachers have no training in working with autism (Rubin 2000). Indeed, most instructors in schools and even at intervention programs specifically geared toward autistic children have little to no relevant training, mostly due to the small number of universities throughout the country that offer such a field of

study (McCabe 2013). Many teachers even express a strong desire for more training, especially relating to adolescent intervention (McCabe 2013). At times, passionate teachers with a will to help autistic children are bound by China's limited awareness and lack of resources.

Social Policy and Current Controversies

Autism, along with many other disabilities and illnesses such as ADHD, schizophrenia, and epilepsy, has been severely stigmatized in Chinese culture (Kelly 2007). There are some deeply rooted cultural explanations for such a social context. In the times of Confucius, the mentally and physically disabled were a part of the lowest social status (Deng et al. 2001). In Mainland China, many still refer to autism and other spectrum disorders as “gudu zheng” which translates to “lonely disease” (Feinstein 2010). Moreover, studies have suggested that families of autistic children have experienced increased levels of stress related to pessimism shame (Wang et al. 2011). This social context and intense stigmatization within Chinese culture often incentivizes families or individuals to hide one's autism or disability rather than treat it. A large number of parents cut their disabled children off from outside social interaction, including schooling for this reason (Wang et al. 2011).

Definition

Chlorpromazine is a prescription drug in the group of first-generation antipsychotics initially FDA-approved for medical use in the year 1957 whose active ingredients are chlorpromazine and chlorpromazine hydrochloride which have the chemical formulas $C_{17}H_{19}N_2SCl$ and $C_{17}H_{19}N_2SCl \cdot HCl$, respectively. This drug is currently only available in generic form. This drug can be used for the treatment of schizophrenia,

bipolar mania, some psychotic symptoms of dementia, and serotonin syndrome. Observed side effects include drowsiness/sedation, parkinsonism, orthostatic hypertension, tachycardia, ECG abnormalities, anticholinergic effects, galactorrhea, weight gain, photosensitivity, rashes, and pigmentation.

Definition

The cholinergic system utilizes acetylcholine (ACh) neurotransmission to regulate memory, arousal, concentration, attention, and consciousness (Sadock et al. 2009). ACh projects from the brainstem neurotransmitter center and basal forebrain to numerous locations, including the prefrontal cortex, basal forebrain, thalamus, hypothalamus, amygdala, and hippocampus (Stahl 2008). ACh is formed from two precursors: choline, synthesized from the diet and intraneuronal sources, and acetyl coenzyme A (AcCoA), made from glucose in the neuronal mitochondria. The enzyme choline acetyltransferase acts on choline and AcCoA to create ACh.

ACh acts on muscarinic and nicotinic cholinergic receptors. Muscarinic receptors are so-named due to their binding preference for muscarine, a toxin found in poisonous mushrooms (Sadock et al. 2009). The five muscarinic receptors are M₁, M₂, M₃, M₄, and M₅, and each has a different anatomical structure. They are G protein-linked and can be excitatory or inhibitory. The M₁ subtype on the postsynaptic neuron is believed to regulate some memory functions. M₁ receptors blocked by antipsychotic medications can induce sedation and some cognitive dysfunction. The presynaptic M₂ receptor is an autoreceptor, detecting excess ACh in the synapse and preventing further release of ACh. M₃ receptors in pancreatic beta cells cause insulin secretion, so antagonism here by atypical

antipsychotics, like olanzapine and clozapine, can result in decreased insulin secretion.

Nicotinic acetylcholine receptors (nAChR) belong to a class of excitatory, ligand-gated ion channel receptors (Sadock et al. 2009). They bind nicotine, the main addictive substance in tobacco smoke. These receptors have subtypes with variable affinities; the highest-affinity subunits are in the thalamus, followed by the substantia nigra, striatum, hippocampus, and entorhinal cortex. There are fewer high-density receptors in the cerebellar, parietal, and frontal cortices. One of the most notable subtypes is the postsynaptic alpha-4 beta-2 subunit, which is believed to regulate dopamine release in the nucleus accumbens (Stahl 2008). This is the likely target of tobacco nicotine in the brain, strongly contributing to tobacco's addictive qualities. The alpha-7 subunit located on the postsynaptic neuron is thought to regulate cognitive function in the prefrontal cortex, whereas the presynaptic alpha-7 subunit on cholinergic neurons provides positive feedback for continued release of ACh. The alpha-7 subunit of the nicotinic receptor located on dopamine and glutamate neurons also regulates the release of these neurotransmitters when ACh is present.

The neurotransmitter ACh is partly regulated by two degradative enzymes, acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE). These enzymes convert ACh back to choline, which is taken back up into the neuron for resynthesis into ACh (Stahl 2008). AChE is considered the main enzyme that inactivates ACh. It is located throughout the brain, along the major projections as outlined above, as well as within the gastrointestinal (GI) tract, skeletal muscle, red blood cells, lymphocytes, and platelets. The highest density of AChE is located in the caudate and putamen, with lower amounts in areas such as the thalamus, hippocampus, and cortices (frontal, temporal, parietal, occipital, and cerebellum). BuChE is also located throughout the brain, mostly in glial cells, but can also be found in the GI tract, plasma, skeletal muscle, placenta, and liver (Stahl 2008). ACh is partly regulated by cholinergic vesicular transporters (VACHT) on synaptic vesicles, which transport ACh into the vesicle (Sadock et al. 2009). The highest densities

of VACHT are also located in the caudate and putamen, as well as the nucleus accumbens. Lower levels of binding occur in the cerebral cortex and cerebellum.

Anticholinergic medications are some of the most well-known medications to act on the cholinergic system. They block the actions of ACh at either the muscarinic or nicotinic receptors, resulting in side effects such as sedation, analgesia, and management of allergies (Sadock et al. 2009). These drugs impact numerous physiological systems, including the ocular, cardiovascular, respiratory, GI, genitourinary, and the central nervous system (CNS). In the CNS, these medications may be initially stimulating, followed by a longer lasting sedative effect. Adverse effects include confusion, disorientation, hallucinations, and memory impairment. In the eye, anticholinergic agents cause paralysis of the ciliary muscle, leading to loss of accommodation, as well as muscarinic blockade of the iris' sphincter muscle, causing pupillary dilation. Additional ocular effects include blurry vision, anhidrosis, and worsened narrow-angle glaucoma. In the cardiovascular system, anticholinergic agents cause tachycardia due to muscarinic blockade of the parasympathetic fibers in the atria. In toxic doses, they can cause intraventricular conduction block. In the respiratory system, muscarinic blockade causes reduced glandular secretion of the smooth muscle, leading to dry mouth. In the GI tract, inhibited parasympathetic control from anticholinergic blockade leads to decreased motility, causing constipation, delayed gastric emptying, and paralytic ileus. In the genitourinary tract, anticholinergic agents relax the smooth muscle of the bladder and ureter, leading to urinary hesitancy, but they are also known to cause urinary retention. Despite their reputation for adverse effects, anticholinergic agents can be therapeutically useful. They are commonly prescribed to prevent or improve extrapyramidal side effects (EPS) caused by dopamine antagonists. EPS reactions include dystonia, akathisia, and parkinsonism. When antipsychotics block dopamine in the nigrostriatal tract, cholinergic activity is increased, resulting in the above-mentioned side effects. Anticholinergic agents reduce the

increased cholinergic activity, restore balance to the dysfunctioning neurotransmitter system, and relieve symptoms of EPS.

From a pathophysiological standpoint, the cholinergic system is most frequently associated with Alzheimer's disease (AD). In AD, there is degeneration of cholinergic neurons in the nucleus basalis due to deposition of amyloid plaque, leading to memory loss (Sadock et al. 2009). AChE inhibitors prevent the destruction of ACh, which prevents further memory loss in AD. Some AChE inhibitors only inhibit AChE, whereas some inhibit both AChE and BuChE. Depending on the individual, responses to these agents vary, but the overall effect is prevention or slowing of disease progression (Stahl 2008). Examples of AChE inhibitors are donepezil, amantadine, rivastigmine, and galantamine. Another disease process implicated in the pathophysiology of the cholinergic system is schizophrenia, as evidenced by the observation that antimuscarinic drugs improve negative symptoms (Sadock et al.). Anticholinergic agents are known to worsen positive symptoms in patients with unstabilized schizophrenia, but they appear to have no effect on positive symptoms in stabilized patients (Sadock et al.). The cholinergic system is also implicated in Parkinson's disease (PD), which results from dopamine deficiency and cholinergic excess. Anticholinergic agents can help reduce parkinsonian tremor via muscarinic receptor blockade, especially in combination with levodopa, a first-line dopaminergic agent used to treat PD.

Historical Background

ACh was the first neurotransmitter to be discovered. The first individual to uncover its existence was Henry Hallett Dale, a British pharmacologist who lived between 1875 and 1968 (Raju 1999). While studying ergot extracts, Dale found that the extracts reversed the effects of epinephrine and concluded that ergot contained tyramine, histamine, and ACh. In 1914, Dale determined that ACh was the "most suitable chemical" for parasympathetic neurotransmission, and coined the

terms "cholinergic" and "adrenergic." Not long after his discovery, a German physician named Otto Loewi (1873–1961) was researching the autonomic nervous system when he discovered the presence of ACh and adrenaline in isolated hearts. The year was 1921, and Loewi was the first individual to underscore ACh's importance in the nervous system. Loewi initially named ACh "vagusstoff," referencing its release from the vagus nerve. These two men shared the Nobel Prize in Physiology and Medicine in 1936 "for discoveries related to chemical transmission of nerve impulse."

Current Knowledge

Impairment of the cholinergic system has been implicated in the pathophysiology of autism. Postmortem studies by Perry et al. (2001) show a 30% reduction of cortical muscarinic receptor binding in the parietal cortex in autistic individuals compared with age-matched controls. Cholinergic neurons in the basal forebrain, an area thought to play a role in attention, are abnormally large and plentiful in children with autism (Baumann and Kemper 1994). A study by Sokol et al. (2002) found low cytosolic choline concentrations as measured by hydrogen proton magnetic resonance spectroscopy in ten children with autism. Imaging studies have also attempted to link neuroanatomical regions of the brain to core domains of dysfunction observed in autism. Individuals with autism have been noted to have significant deficits in face perception (Grelotti et al. 2002; Schultz 2005), which is believed to play a notable role in social interaction. The neuroanatomical region linked to facial recognition is the fusiform gyrus, which contains the visual pathway. This pathway is regulated by the cholinergic system, suggesting a possible causal relationship between the cholinergic system and autistic social impairment. A study by Suzuki et al. (2011) used positron-emission tomography (PET) and a radiotracer to examine AChE activity in 20 autistic adults compared to 20 age- and IQ-matched controls. The results showed a deficit in cholinergic innervations of the fusiform gyrus in the autistic

subjects, suggesting a possible explanation for social impairment in autism.

There is evidence to suggest that specific cholinergic receptor subtypes play a role in the pathology and symptomatology of autism. It is believed that deficits in alpha4-containing receptors predominate in autism (as well as in Alzheimer's disease), whereas other receptor subtypes are associated with other disorders, like the alpha-7 subtype and schizophrenia (Graham et al. 2002). These observations may lead to drug development targeting specific nicotinic receptor subtypes for alleviation of symptoms in autism. Similarly, a theory by Lippiello (2006) suggests that autism is a disorder of "overfocused attention," unlike attention-deficit/hyperactivity disorder (ADHD), which can be described as a disorder of "underfocused attention." These two disorders theoretically sit at opposite ends of a spectrum with reversed neurophysiological mechanisms underlying their pathophysiology. Lippiello hypothesizes that because nicotinic cholinergic agonists have been shown to improve the symptoms of ADHD (Levin et al. 2001); perhaps nicotinic cholinergic antagonists may ameliorate the symptoms of autism. The concept of nicotinic receptor antagonists treating autism has not yet been explored in the literature, but these concepts may lead to future initiatives in studying the relationship between the anticholinergic system and autism.

Medications affecting the cholinergic system, particularly AChE inhibitors, have been studied to treat symptoms associated with autism. These agents increase ACh in brain regions related to attention and memory, such as the cerebral cortex and basal forebrain (Yoo et al. 2007). Amantadine is a drug approved for the prophylaxis of influenza A, but is commonly used in the treatment of PD and EPS due to its antiparkinsonian effects (Sadock et al. 2009). A double-blind, placebo-controlled study examined the effects of amantadine in 39 autistic children aged 5–19 years (King et al. 2001). The clinician-rated Aberrant Behavior Checklist rating scale (ABC) showed statistical significance in the amantadine-treated group within the domains of hyperactivity and inappropriate speech

(Blakenship et al. 2011). The parent-rated ABC did not show statistically significant improvement between the amantadine and placebo groups. Galantamine, another AChE inhibitor, was examined in 20 males with autism in a double-blind, placebo-controlled study (Niederhofer et al. 2002). Using the ABC as a dependent measure, there were decreases in the domains of irritability, hyperactivity, inadequate eye contact, and inappropriate speech. Despite these promising observations, studies examining the effect of other AChE inhibitors have found dissimilar results. A double-blind, placebo-controlled study by Handen et al. (2011) looked at the effect of donepezil in 34 children and adolescents aged 8–17 years (IQ > 75). The results showed some improvement on a number of measures of executive functioning, but there were no statistically significant differences between the donepezil and placebo groups. The researchers concluded that short-term treatment with donepezil may have limited impact on cognitive functioning in those with autism.

Retrospective and open-label trials are of limited utility in demonstrating effectiveness and safety of a medication due to their lack of experimental design, but they offer a glimpse of possible directions that can be taken in the treatment of symptoms associated with autism. A retrospective study by Hardan and Handen (2002) examined the effects of donepezil, an AChE inhibitor, in the treatment of 8 children with autism, aged 7–19 years. The study found a significant decrease in irritability and hyperactivity according to the ABC, although attention and memory were not measured. An open-label study by Nicolson et al. (2006) examined the effects of galantamine, an AChE inhibitor and nicotine receptor modulator, in the treatment of 13 children with autism. Galantamine demonstrated reductions in parent-rated irritability and social withdrawal on the ABC, improvements in emotional lability and inattention on the Conners' Parent Rating Scales-Revised, and reduced anger on the clinician-rated children's Psychiatric Rating Scale. Hertzman (2003) reported three cases where galantamine promoted verbalization in adults with autism.

Another open-label study by Chez et al. (2004) examined the AChE inhibitor rivastigmine tartrate and found significant improvements in scores of various measurements, including the Childhood Autism Rating Scale, Gardner's Expressive One-Word Picture Vocabulary Test, and Conners' Parent Rating Scale.

Future Directions

Future directions for research into the relationship between the cholinergic system and autism will likely involve investigating cholinergic receptor subtypes, neuroimaging, and pharmacologic treatment development. Cholinergic receptor subtypes occur at variable concentrations in the brain and are implicated in the pathophysiology of autism. Exploring their influence on attention, memory, and cognition, as well as the core diagnostic domain of social impairment, will likely be a continued area of research. Neuroimaging of these receptors will continue to map areas of neuroanatomical dysfunction in autism. Medications affecting the cholinergic system could be further explored as treatments for autism given the mixed results seen in existing studies. Double-blind, placebo-controlled trials are required to draw conclusions about medication safety and efficacy, and currently there are minimal studies examining the effectiveness of AChE inhibitors. Short-term studies of AChE inhibitors have shown mixed results, so it may be of benefit to employ them for longer periods before drawing definitive conclusions about their efficacy. Lastly, the study of nicotinic cholinergic receptor antagonists as a treatment for autism is another possible, untapped direction.

Christopher Gillberg

Helen Minnis

Institute of Health and Wellbeing, University of Glasgow, Glasgow, UK

Major Appointments

(Institution, Location, Dates) University of Gothenburg (from 1983) and Institute of Child Health, London (from 2004) and University of Glasgow (from 2003)

Major Honors and Awards

Fernström Prize for Medicine in 1991, Ingvar Award in 1995, The Ronald McDonald Major Award for Paediatrics in 1998, Ågrenska Major Medicine Prize in 2001, Philips Nordic Prize in

2004. In 2009, Carl XVI Gustav of Sweden presented Gillberg with The King's Medal of the Seraphim order for his contributions in the field of child and adolescent psychiatry. He received the Dahlberg award for his genetic research and the Life Watch Award for Autism Research in 2010. In 2012 he was awarded one of Sweden's most prestigious scientific honors: the Söderberg Prize for Medicine ("Little Nobel Prize"). In 2016 he was presented with the INSAR Lifetime Achievement Award at the International Meeting for Autism Research (IMFAR).

Landmark Clinical, Scientific, and Professional Contributions

Since the early 1980s, Christopher Gillberg has been publishing practice-changing work on autism: his first paper on the subject is a typically rigorous population-based study on autism and maternal age (Gillberg 1980). His studies have always been highly clinically relevant and, wherever possible, population based, and this has allowed him to see trends in autism spectrum disorders (ASD) that others have missed. He was the first to notice that anorexia nervosa and autism might be related (Gillberg 1983a), and this was later borne out in population-based research. Early in his career, he demonstrated that autism was a more common disorder than first thought (Gillberg et al. 1991) – a finding that was not generally believed at the time, but which is now widely recognized (Lundström et al. 2015).

With child neurologist Mary Coleman, he demonstrated that autism is really "the autisms," with a large proportion of autism diagnoses explained by a multitude of different etiological mechanisms (Gillberg and Coleman 1992) – and that different underlying etiologies might be manifested in different behavioral phenotypes (clinical presentations). This work stimulated an interest in the biological underpinnings of ASD, and a collaboration with Marion Leboyer and with Thomas Bourgeron and colleagues at the Institut Pasteur has elucidated a range of genetic findings that have demonstrated the importance of problems in synapse and cell membrane functioning in

people with autism (Jamain et al. 2003). These findings may well usher in a new era of treatment for ASD.

His rigorous epidemiological approach has shown beyond doubt that autism is a lifelong condition (Hofvander et al. 2009) that is rarely “pure”: co-occurrence with other disorders and problems is the rule (Gillberg 1983b); children with autism are more likely than typically developing children to suffer from attention deficit hyperactivity disorder, tic disorders, and learning and motor problems (Gillberg 2010). An important corollary of this is that “pure” autism may not be problematic across the lifespan – that difficulties experienced often come from the comorbidities, not only from the autism “per se” (Gillberg and Fernell 2014).

Short Biography

As a young boy, Christopher Gillberg’s first wish was to be a film director, and his intense creativity was also expressed in music and painting. However, he was also exceptionally talented academically and had the best exam results in Sweden at the end of his school career. Because he was unusually young when leaving school, he could not enter film school but, instead, was encouraged toward a career in medicine – a field that has since benefited from that intense creativity.

He married Carina Gillberg in 1969, and they have five children. Carina Gillberg is also a child and adolescent psychiatrist, and they have published many papers together, including the widely used Gillberg and Gillberg criteria for Asperger’s syndrome (Gillberg and Gillberg 1989).

As a young doctor, Christopher was asked to oversee a unit for young people with learning disabilities, and his lifelong fascination with autism was born. At that time, autism was usually treated with psychoanalysis, and the frustrations of this approach to what struck Christopher as a brain-based disorder sparked his interest in research.

Throughout his career, his main clinical and research base has been the University of Gothenburg, but his career has been characterized by many fruitful international collaborations. In

1993 he was Fulbright visiting professor at New York University Medical School, and he holds, or has held, full, visiting, or honorary professorships at the Universities of London, Glasgow, Edinburgh, Strathclyde (Glasgow), Kochi (Japan), Odense (Denmark), Bergen (Norway), San Francisco, the Institute of Child Health (London), and the Institut Pasteur (Paris).

He has published more than 650 peer-reviewed scientific papers (more than 600 are on PubMed), and the contribution of his research to clinical practice and social policy is both broad and profound.

Alterations in chromosome structure or number

Structure

Humans have 22 pairs of autosomes (nonsex chromosomes) and 1 pair of sex chromosomes (XX or XY). Genes are organized in a characteristic pattern on each chromosome. Any disruption of the total number of chromosomes, or the order or amount of genetic material on a given chromosome, is considered to be a chromosomal abnormality. Chromosomal abnormalities occur in about 1 in 150 live births and are the most common cause of intellectual disability and loss of a pregnancy (Jorde et al. 2010). An example of a syndrome caused by disruption of chromosome number is Down syndrome, the most common genetic cause of moderate intellectual disability, which is due to having three copies of chromosome 21, or trisomy 21 (Nussbaum et al. 2007).

In addition to the gain or loss of an entire chromosome, rearrangement of the order of genetic material on a chromosome, or the gain or loss of part of a chromosome, may result in a genetic disorder. Chromosomal abnormalities may be either *balanced* or *unbalanced*, depending on whether the particular alteration results in no net change in the total amount of genetic material, or a net change, respectively. For example, a *translocation* is a chromosomal rearrangement

that occurs when segments of nonhomologous chromosomes break off and are transferred from one chromosome to another. In a *reciprocal translocation*, there is an even exchange of genetic material between the two chromosomes. Other abnormalities include *deletions* and *duplications*, which result in the net loss or gain of genetic material, respectively, and *inversions*, which occur when two breaks occur on the same chromosome, and the piece that is cut out reinserts in the same location, but in the opposite direction (Jorde et al. 2010).

Such abnormalities of chromosome structure may be inherited, or can be new mutations, i.e., occur *de novo*, in the parent's germline. Such abnormalities tend to occur at regions with repetitive sequences of DNA and are due to errors in recombination between homologous chromosomes. Trisomies of the autosomes are most often due to errors in nondisjunction that occur during meiosis, the risk of which increases with maternal age. In general, because most genes in the human genome play a role in the development of the central nervous system, the larger the region of the chromosome that is disrupted, the more genes that are affected, and the greater likelihood that the chromosomal abnormality will result in a developmental disability (Jorde et al. 2010; Nussbaum et al. 2007).

Changes in chromosome number are clearly observable by karyotype. Similarly, large chromosomal abnormalities, such as duplications or deletions that cause the gain or loss of over a few million base pairs, can be detected by the banding pattern on a high-resolution karyotype (Nussbaum et al. 2007). However, the detection of smaller duplications or deletions was not possible until the development of more advanced techniques, including *fluorescence in situ hybridization (FISH)* and *comparative genomic hybridization (CGH)*. FISH utilizes probes that bind to specific regions of DNA to identify the precise location of a chromosomal break point and can be used to identify the genes that are disrupted in that region. CGH involves the binding, or hybridizing, of a patient's genome to a control genome, or in array-based CGH, which improves resolution, to a microarray that contains probes corresponding to

a control genome such that it is possible to detect net gains or losses of chromosomal regions. However, it is not possible to detect abnormalities such as balanced translocations using CGH, because there is no net change in the amount of genetic material in the patient's genome compared to the control genome (Jorde et al. 2010; Nussbaum et al. 2007).

These advances in molecular cytogenetics improved our ability to detect smaller abnormalities in chromosome structure, revealing regions of chromosomes that are associated with specific developmental syndromes, and in some cases, an increased risk of autism spectrum disorders (ASD) (see below). Therefore, investigations of abnormalities of chromosome structure in developmental syndromes have shaped the course and current approach to research in the genetics of ASD (Hoffman and State 2010). For example, Prader-Willi and Angelman syndromes are caused by a microdeletion (loss of less than five million base pairs of DNA) of chromosome 15q11-13. Inheritance of the microdeletion from the father results in Prader-Willi syndrome, while inheritance of a microdeletion in the same region of the maternal chromosome leads to Angelman syndrome, due to imprinting in this region. In addition, DiGeorge syndrome, also called velocardiofacial syndrome, which causes intellectual disability, and craniofacial and heart defects, is caused by a microdeletion of chromosome 22q11.2 (Nussbaum et al. 2007). Structural abnormalities of each of these chromosomal regions are associated with an increased risk of ASD (see below) (Hoffman and State 2010).

Function

The study of chromosomal abnormalities in ASD is particularly germane because individuals with idiopathic autism are more likely than unaffected individuals in the general population to have abnormalities of chromosome structure (O'Roak and State 2008). In particular, abnormalities in specific chromosome regions occur at a higher frequency in individuals with ASD. For example, 1–3% of affected individuals were found to have

maternally inherited duplications of chromosome 15q11-13 (Veenstra-VanderWeele and Cook 2004). Additional chromosomal regions that are more often disrupted by structural abnormalities in ASD include 16p11 and 22q11, both of which have been associated with a range of psychiatric disorders, consistent with the concept of pleiotropy, which is an emerging theme in the genetics of ASD (Hoffman and State 2010; State and Levitt 2011).

Chromosomal abnormalities that are identifiable by cytogenetics occur in an estimated 6–7% of individuals with ASD and in a higher percentage of individuals with ASD who have dysmorphic features and intellectual disability (Abrahams and Geschwind 2008). The likelihood of finding a chromosomal abnormality depends on the resolution of the cytogenetics technique used. For example, approximately 2–5% of individuals with ASD have a chromosomal abnormality identifiable by karyotype (Reddy 2005; Schaefer and Mendelsohn 2008; Shen et al. 2010). Studies have found that yield improves with increasing resolution of the clinical test such that clinical microarray has a higher rate than karyotype of detecting chromosomal abnormalities, though, as discussed, the limitation of this CGH-based test is that it cannot detect balanced translocations (Shen et al. 2010). In addition, the use of FISH for regions where structural abnormalities are more likely to occur in ASD is also likely to improve yield (Reddy 2005).

Recent guidelines recommend obtaining a karyotype as well as testing for fragile X syndrome (FXS) in the evaluation of all individuals with autism spectrum disorders (ASD) (Lintas and Persico 2009; Schaefer and Mendelsohn 2008). Tests for FXS in children undergoing a genetic evaluation for ASD are positive in up to 5% of cases (Reddy 2005; Schaefer and Mendelsohn 2008). Recent studies have suggested that higher resolution cytogenetics tests should also be included as a standard part of the evaluation of a child with ASD, given the increased yield of the higher resolution tests (Reddy 2005; Shen et al. 2010). One of the challenges of conducting these tests remains the limitation in our ability to interpret the findings, particularly given that structural

abnormalities may be inherited or *de novo*, and given the pleiotropy of some of the regions implicated in ASD.

As the technology used to detect chromosomal variation has improved in recent years, our ability to identify abnormalities in chromosomal structure in the research lab has advanced considerably such that it is now possible to detect accurately changes that are in the kilobase range. These submicroscopic gains or losses of genetic material are called *copy number variations* (CNVs). Since 2005, studies of CNVs have made a major contribution to our understanding of the genetic architecture of ASD. Sebat and colleagues were the first to identify an increased association of *de novo* CNVs in families with one affected child (simplex) compared to multiplex families, in which more than one child has autism (Sebat et al. 2007). This finding is consistent with the *rare variant hypothesis*, which predicts that individually rare, *de novo* variation accounts for the risk of autism in families where only one child is affected. At the same time, studies of CNVs in autism have shown that they have similar properties as other types of genetic variation. That is, CNVs can either be inherited or arise *de novo*, common or rare, and may or may not be associated with an increased risk of ASD (Hoffman and State 2010). Although CNVs that are associated with ASD are individually rare, e.g., occur in only 1–2% of individuals with ASD, as a group, these may occur in at least 10–20% of affected individuals (Abrahams and Geschwind 2008).

Pathophysiology

One approach of current research is to utilize the findings of rare chromosomal abnormalities as a route toward understanding the underlying pathophysiology of ASD. Therefore, known genetic syndromes that are associated with an increased risk of symptoms that are similar to those found in ASD may be instrumental in highlighting regions of chromosomes, and therefore, individual genes, that may predispose to ASD. Elucidating the functions of these *candidate genes* can lead us to a

better understanding of biological mechanisms that may be causative.

It is important to observe that while any of the chromosomal abnormalities discussed above, e.g., 15q11-13, are individually rare in idiopathic ASD, symptoms consistent with a diagnosis of ASD may occur at relatively high frequencies in individuals with known genetic syndromes. For example, more than 40% of children with Angelman syndrome and 25% of males with FXS have an ASD (Abrahams and Geschwind 2008). FXS is an important example of how the identification of a cytogenetic abnormality associated with an increased risk of ASD can advance our knowledge of pathophysiology. FXS is the most common inherited cause of intellectual disability (Cornish et al. 2008). The genetic etiology was first identified because the mutation produces a constriction in the X chromosome that is visible by light microscopy. Subsequent studies found that FXS is caused by disruption of a single gene, *fragile X mental retardation 1* (*FMRI*), by a trinucleotide repeat expansion, and that this gene produces a protein that regulates the transport and activation of other molecules that play important roles at the synapse of nerve cells. Further analysis of the function of *FMRI* revealed a potential mechanism for reversing the adverse effects of the mutation pharmacologically (Cornish et al. 2008).

Importantly, *FMRI* was identified as a candidate gene in ASD due to the increased risk of ASD in individuals with FXS, even though mutations in *FMRI* are individually rare in idiopathic autism. Therefore, one approach to the identification of novel candidate genes in ASD that is based on the rare variant hypothesis is to find rare cases of *de novo* chromosomal abnormalities in affected individuals and to identify precisely which genes are disrupted at the break points. This approach has led to crucial discoveries, including the identification of the following susceptibility genes: *contactin-associated protein-like 2* (*CNTNAP2*), *contactin 4* (*CNTN4*), *neuroligin 4X* (*NLGN4X*), and *SH3 and multiple ankyrin repeat domains 3* (*SHANK3*) (Bakkaoglu et al. 2008; Durand et al. 2007; Fernandez et al. 2004; Jamain et al. 2003). While disruptions of these genes are rare in idiopathic autism, their identification as candidates has been

important in elucidating the pathophysiology of ASD by illuminating potential biological mechanisms, such as synapse formation and function.

In recent studies, CNVs serve a similar function as large chromosomal disruptions, highlighting genes that are likely to play a role in ASD. However, one of the challenges that current researchers face is the high degree of structural variation that exists throughout the genomes of affected and unaffected individuals, which often confounds the interpretation of CNV studies. Nonetheless, it is clear that abnormalities in chromosome structure have the potential to offer insight into the genetic etiology of ASD. By following the leads from studies of chromosomal abnormalities, current research aims to illuminate common mechanisms involving candidate genes and, thereby, to identify new approaches for treatment.

Chromosome 15q11–q13

Abha R. Gupta

Developmental-Behavioral Pediatrics, Child Study Center, Yale University, New Haven, CT, USA

Synonyms

[Angelman/Prader-Willi locus](#)

Definition

This region on the long arm of chromosome 15 is adjacent to the centromere and is 14.6 million bases in size. It spans genomic coordinates 19,000,001–33,600,000 (GRCh37/hg19 assembly, UCSC Genome Browser). It contains numerous genes, some of which are subject to genomic imprinting, a phenomenon by which a gene(s) is silent on either the maternally or paternally transmitted chromosome. Mutations in this locus are responsible for Angelman and Prader-Willi Syndromes. Deficiency of the maternally expressed *UBE3A* gene causes Angelman Syndrome. While it has not been definitively determined which gene(s) in the interval cause PWS, deficiency of paternally expressed small nucleolar RNAs (snoRNAs) has been considered the leading suspect.

Other genes at this locus include those which encode subunits of the GABA receptors, *GABRB3*, *GABRA5*, and *GABRG3*. *CYFIP1* encodes a protein, which interacts with the Fragile X mental retardation protein, FMRP (Schenck et al. 2001). *SNRPN* encodes a small nuclear ribonucleoprotein that is involved in mRNA processing. The upstream untranslated region (5'UTR) of this gene is an imprinting center, which helps to determine the parental imprint of the chromosome (Saitoh et al. 1996).

The entire region is prone to complex rearrangements in chromosomal structure and has been implicated in Autism Spectrum Disorders (ASDs) as well as in schizophrenia, epilepsy, and intellectual disability. Within the interval, there are a number of specific points that are particularly likely to serve as the boundaries for changes in chromosomal structure. These are called breakpoints and have been numbered BP (breakpoint) 1–BP5. Duplications of the maternal chromosome extending from either the centromere or BP1 to BP5 are among the most common changes in chromosomal structure identified in ASD (Sanders et al. 2011). A high proportion of patients with duplications at this locus meet diagnostic criteria for ASD (Abrahams and Geschwind 2008). Conversely, in some clinical

ASD cohorts, up to 1% of patients show maternal duplications of this interval (Sanders et al. 2011). In addition, deletions of the BP1–BP2 region and BP4–BP5 regions have been associated with schizophrenia, deletions of BP4–BP5 have been implicated in epilepsy and intellectual disability, and duplications within the BP4–BP5 interval have been identified in patients with ASD and intellectual disability and are also not infrequently seen in unaffected individuals (Sanders et al. 2011).

Cingulate Cortex

Michael J. Crowley
Developmental Electrophysiology Laboratory,
Yale Child Study Center, New Haven, CT, USA

Definition

The cingulate cortex is a brain region located in the medial portion of the cortex, just above the corpus callosum, continuing through the cingulate sulcus. Traditionally, the cingulate cortex is divided into an anterior portion or anterior cingulate and a posterior portion or posterior cingulate. Broadly, the anterior cingulate is involved in self-regulatory and executive control functions, social and emotional processing, and respiratory control. The posterior cingulate is thought to be involved in supporting internally directed thought. As a key node of the default mode network, the posterior cingulate cortex is thought to play a role in modulating the dynamic interplay between the default mode network and attention networks providing for efficient allocation of attention.
